shown that it is consistently out performed by a plain old dipole. I was able to make contacts with the Lazy H, and I did get some good reports with it. However, when I switched to the plain old wire dipole the dipole was consistently the stronger performer. I have not tried the end fed Lazy H design with a 180 degree twist and the 1/4 wave matching stub yet.

Hi Michael,

All very true, but be careful of the conclusions you thinks this leads
you to. For instance:

>There are
>many web pages touting the supposed gain of the Lazy H with EZNEC
>plots posted as supporting evidence, but real world performance has
>shown that it is consistently out performed by a plain old dipole.

The Lazy H, in professional installations known as Sterba Curtains,
are THE antenna of the big gun Shortwave Broadcasters. Engineers,
stations, and their backers looking at field data do not erect costly
antennas without good judgment. In the past, we have had contributors
here who have designed for these big guns.

Now, as to what you see as "evidence" on the Web in the form of EZNEC
software reports (something I've been using for nigh-on 20 years) has
to be looked at in the details, and the details that are significant:
1. The presence of ground
2. The quality of ground
3. The antenna elevation above ground
4. The presence of conductor loss
5. Transmission line specification
6. Transmission line drive
7. The load Z
8. The system gain (or loss)
at a minimum. That is a lot of detail to hold in the mind while
trying to compare two antennas, much less 3, 4, or 5.

One of the glaring mistakes between the outcome to this and "reality"
(and this undoubtedly conforms to your experience) is that the
placement of the source (transmitter) in software is vastly different
than the placement of the transmitter (source) in physical reality.

For instance, the twist in the line between elements is to enforce a necessary phase relationship so that you can fee it at the bottom. Otherwise you can go with a non-twist if you feed it in the middle. The design varies in particulars there. So what? You can feed either a twisted connection, or a non-twisted section in the middle; BUT for the second version, the line back to the transmitter MUST BE dressed AWAY from the middle of the interconnecting line. Proximity will confound everything. Proximity for this second choice is almost guaranteed in a casual installation where an EZNEC "schematic" of the system offers only a blob called "source" in a spot of convenience that does not exist in reality.

So, the long and short of it is:
Do not feed in the middle of the interconnecting line.
Observe proper phasing requirements.

You can perform your own EZNEC analysis using the free version. The benefit of this is you can control all the variables, adjust items 1 through 6 in the list above, and you can replicate your experience. Doing this will also reveal what you need to do to optimize your antenna.

Maybe.. depends on the antenna.

But consider that they might actually have a 75 ohm impedance, which
will be close to what you need.

The W8JI web page goes to considerable length to bash the end fed Lazy H with the twist, but since the real world performance of the center fed Lazy H is less than stellar I'll have to give it a try.

There is one thing the center fed Lazy H did better than the dipole and the extended double zepp. When I applied RF to the center fed Lazy H four of my outside motion sensor flood lights would come on. I guess if I wanted to go outside at night I could just switch to the Lazy H, key the mic, and save myself a trip to the light switch. ha ha

W8JI bashing the end fed Lazy H with the twist

Hi Michael,

As I offered, feed at the bottom, and observe proper phase
relationships. This page you reference also makes a note of those
relationships being improper will point your radiation straight up,
and straight down. Go figure - this is quickly revealed by EZNEC.

> When I applied RF to the center fed
>Lazy H four of my outside motion sensor flood lights would come on.

This is 100% rock-solid proof of Common Mode current on your
transmission line. This condition will cause extreme grief in trying
to match your transmitter to. It also skews the radiation/reception
lobes BIG-TIME.

Does this sound familiar?

The problem probably comes from your tuner's BalUn having a connection
to earth ground.

Solution to that (for all "balanced," horizontal antennas):
1. Use Coax.
2. Put a choke style (W2DU) BalUn at the antenna (ask about this).
3. Add a second choke a quarter wave away from the feed point.
OR
1. Fix the ground path inside your tuner (not as simple as it may
seem, unfortunately - in fact it can be an Herculean task - it may not
even be doable).
2. Obtain (purchase or build) the proper tuner.

Your antenna will then tune with vastly more grace, and you may even
find it performs much like common sense would expect. As I said
earlier, there is a world of experiential details that can kill an
EZNEC model's prediction - and it isn't the fault of EZNEC.

I would go with a 2M QUAD, Very easy to build cookbook style. on site
from scrounged materials. Ive used one from an apartment shooting
through a balcony door. PVC mast was made from a couple of scrap
pieces I got from the handy man. Pipe was selected so that one would
slide inside the other. Apply padding to ends to protect ceiling and
floor Think I wedged a piece of cardboard to lock the slip joint.
Inovate as required. The quad can be asily put together with out
benifit of test equipment and expected to function reasonably well
without additinal tweaking. However a knockdown Yagi can be buit ahed
of time and the elements stored inside the boom. Both are very handy.

I should probably invest in an antenna matcher. Think I've got one for 11m,
but that wouldn't do me much good. :-)

Jimmie

Thanks, Jimmie. I was wondering about the quad, what kind of a pattern it
put out, etc. Gotta hit Google for some research.

> Cecil, you are correct!!!

Thanks Walt, it would be interesting to see what else about which I am correct. W7EL has a food-for-thought publication with one section about reflections from the source. His source has a 50 ohm source impedance, by design, so any dynamic load pulling experiment should result in zero reflections from the source. Question is, does it?

http://eznec.com/misc/Food_for_thought.pdf

The "forward and reverse power section" is at the bottom of the page. Using the dynamic load pulling method, do the results always indicate 50 ohms for the source impedance no matter what is the load and/or the transmission line length? If not, the method yields invalid results.

IMO, it is a gross error to presume that all redistribution of energy is a result of reflections. In W7EL's example, there are no reflections from the source yet it is obvious that energy is being redistributed from the source back toward the load in some cases but not in other cases. IMO, destructive/constructive interference must be taken into account in order to explain the results. Yet, no one except yours truly has even mentioned interference effects as a method of redistributing energy.

Anyone interested in understanding the role of interference at impedance discontinuities in transmission lines is welcome to read my article at:

Right on, Cecil. The article you URL'ed is the most clear and accurate paraphrasing of my presentation of the subject in 'Reflections'. Nowhere else is the subject clearly defined concerning destructive and constructive interference in relation to impedance matching and 100% re-reflection. I hope RF engineers everywhere can realize that optics and RF are indeed using the same principles of electromagnetics, and therefore follow exactly the same rules.

However, I would like for you to add one more reference to your article, an article I published in QEX that proves Steve Best's QEX three articles wrong. It appeared in the Jul/Aug 2004 issue, entitled, "A tutorial Dispelling Certain Misconceptions Concerning Wave Interference In Impedance Matching."

Let me know here whether you have a copy of my QEX article. If not, I'll email you a copy.

Walt, W2DU

If anyone else on this thread would like a copy of my QEX article please let me know by email. My email address is shown above.

Hello Cecil,

When a source behaves like a 50 Ohms source, it will not rereflect the
reflected power back to the load. In other words the forward power
generated by the source will not change when changing the load. The
reflected power that is absorbed by the source may result in increase
or reduction of power dissipation of the active device. It all depends
on the change of the integral of V*I (for the active device).

With regards to load pulling, output impedance of an amplifier may change depending on the rate of change of the load. As I mentioned earlier, manual load pulling may result in change of supply and bias voltage and current. Average Voltage and current have time to settle to the new load condition.

In case of load pulling where the load changes relatively fast, but well within the matching section's bandwidth (as is the case for the off-carrier signal injection method) supply and bias voltage change may be less due to decoupling capacitance.

In simulation this can easily be seen by applying a load step change and observe the envelope and phase response versus time. Of course this requires you to model your power supply and bias circuit correctly. You may see a slow step response that cannot be explained by the bandwidth of the matching network.

To walt:
I didn’t see your announced comment to my last post (regarding the forward/reverse power mathematics), did I missed it?

With kind regards,

Wim

Hello Wim,

I hadn't yet given you my final understanding of it. I understand the
voltage divider action, but I don't yet understand the following quote
from you:

"When terminated according to the numbers above the socket ("100W
into
50 Ohms"), this results in 100W (Vout = 212.1*50/(50+100) = 70.7V,
just a voltage divider consisting of 100 Ohms and 50 Ohms)."

The portion I don't understand is the mathematical basis for:

"(Vout = 212.1*50/(50+100) = 70.7V,"

And Wim, on your last post above I agree that if the source is 50 ohms with a real resistor, as in the classical generator used in text books. However, are you not aware that the output resistance of the RF power amp is R = E/R that appears at the output. Since this R is non-dissipative it re-reflects all the reflected power. I have proved this to be true in the experiment I presented with the Kenwood TS-830S presentation that I'm sure you have a copy of.

Consequently, the RF power amp is not going to absorb the reflected power.

At this point my email server is down, but I'll forward a copy of my QEX article ASAP.

Walt

Richard F is, of course, correct. You can just as well do it for DC:
2V O.C., 1 ohm source will deliver 1A, 1V, 1 watt to a 1 ohm load.
For a 2 ohm load, the current is 2/3 amp; the power is 8/9 watt. For
an 0.5 ohm load, the current is 4/3 amp; the power is 8/9 watt. It's
not terribly difficult to show, for the AC case, that the same is true
for any 2:1 load, regardless of phase angle--trivial, in fact, if you
accept that the SWR along a lossless TEM line is constant.

Cheers,
Tom

My apology, Wim, the equation I quoted in my last post is incorrect--I mean't to say R = E/I, not E/R. Sorry.

Walt

Of course, with pretty much any decently designed power amplifier, no matter the frequency, included protection circuits will limit the dissipation and voltage in the critical areas (e.g., the output active devices). Loads become disconnected or shorted sometimes; winds blow stray wires or tree limbs across antennas. Through a piece of transmission line, such a change can reflect back to become any possible phase angle, and any of a very wide range of magnitudes, at the amplifier's output.

Though it's a red herring typical of audio-speak, most modern high fidelity audio amplifiers have a very low output impedance, a small fraction of an ohm, so they can claim a high damping factor. Off topic: the reason it's a red herring is that the impedance of the speaker connected to the amplifier must be included to figure the damping, and that impedance (even just the DC resistance of voice coils) changes by considerably more than the amplifier's output impedance (resistance) just because of heating on audio peaks.

Especially when reactive components (inductors and capacitors) couple power between a source and a load, you can get stresses--voltages and/or currents--well beyond what's safe when you try to operate the source into a load it's not intended to handle. That's true even when the net power delivered to the load is considerably LESS than the rated output power of the source. Wim's example of the class-E amplifier is true enough, but it's not necessary to ask the source to deliver more net load power than it's rated to deliver, to establish conditions that cause trouble. Thus, even sources that have an output impedance at or very close to the rated load impedance will have circuits to protect against loads that could destroy things inside the amplifier.

Cheers,
Tom

Hello Walt,

We have just a voltage source of 212Vrms with 100 Ohms in series. This is all in a black box and called my PA. That black box has a UHF socket and that mentions "100 W into 50 Ohms".

When you connect 50 Ohms to the SO 239 socket, you get a voltage divider. 2/3 of the EMF is across the internal 100 Ohms and 1/3 is across the 50 Ohms load. This results in 70.7V across the load (so 100W).

Does this make sense?

Wim

Hello Tom,

I agree with your statement. If you have a CLC LPF section that
introduces about 90 degrees phase delay (see it as a quarter wave
section) and it looks into an open load (so zero power is delivered
to this open load), this will result in a low impedance at the input
of the CLC network. If the plate is connected at this CLC network,
the plate's dissipation will greatly increase.

> amplifier.

I also fully agree on this one.

I'm going to slip a mickey into this by a careful, editorial change of
focus BACK to the subject line.

Though it's a red herring typical of Ham-speak, most modern retail
100W RF transmitters for amateur service have a very low output
impedance, a fraction of an ohm [editorial: until, of course, it goes
to the Z transformer that precedes the bandpass filter].

It must be a rare condition for which there is a transition frequency
below which audio amps source rated at sub Ohm Z feeding loads up to
10 times the sub-Ohm design work - and above which retail Amateur
transmitters at loads up to 10 times the sub-Ohm design do not work
[editorial: without that Z transformer]. Curious logic.

I wonder if that works (sic) backwards? Would the RF deck's finals
feed a speaker with audio with equal power performance of the Audio
amp? Both are sub-Ohm sources, and the RF deck certainly has the
bandwidth.

I await the specification of this transition frequency and the
analysis of how the 100W RF final deck would fail to supply 100W audio
(however crummy it may sound).

Any problems that might arise for the retail Ham transmitter are
already handled by protection circuitry so that's a wash.

Yes Wim, I understand your black box, and the voltage-divider action that occurs when terminated into 50 ohms. But you didn't answer my question, as you normally don't do. So I'll ask it again, as I did in my previous post:

"(Vout = 212.1*50/(50+100) = 70.7V," I asked for the mathematical basis for this equation. I agree that it's mathematically correct, but 212.1 is voltage, or E, but where does 212.1*50 come from? The equation appears to be of the form E/R = E, which is absurd. In what equational form is this equation? I'm trying to learn here.

I apologize for stepping in, Walt, but, maybe this will help:

Vout = 212.1 * (50/(50+100))

In other words, Vout is equal to Vsource times the divider ratio.

I know you know this. I think you just misread it.

Cheers,
John

Walt,

First you should change language, because if you don't understand something, it is not always the other party who is wrong.

For a voltage divider:

Vout = Vin*R1/(R1+R2).

R1 is the lower resistor , here 50 Ohms, R2 is the upper resistor, here 100 Ohms (inside the black box). I can't make it easier. Vin = 212.1 Vrms.

Wim

Thank you for the clarification, Wim. I was unaware of that equation relative to voltage dividers. I'm going to have to do some thinking on that equation before I'll understand the relevance of the numerator, or how it relates to the calculation.

Thank you for stepping in, John, as from you and Wim I understand that that equation represents the voltage-divider circuit. However, I'm still agonizing over the numerator in the ratio. I just can't fit it into the voltage-divider concept. Gimme a little time and it will probably sink in.

Richard, the text below represents real world better:

"Though it's a red herring typical of Ham-speak, most modern retail
100W RF transmitters for amateur service require to see a very low
impedance at their drains/collectors, a fraction of an ohm
[editorial: until, of course, it goes to the Z transformer that
precedes the bandpass filter]."

A push-pull 100W PA (non-switching, just a linear amplifier) fed from
13.8 Vdc will produce a voltage swing of about 20Vp at the primary of
the wide band impedance transformer. I know it can be somewhat more,
but with increased IMD. To extract 100W, you need to create a 2 Ohms
load between the collectors (or drains).

This 2 Ohms has no relation with the actual output impedance of the active devices (as this depends on the impedance seen from the base/gate, semiconductor process, amount of saturation, etc).

With kind regards,

Wim

Where is the reflected power that is "absorbed by the source"
dissipated? How can a "reduction of power dissipation" be the result?
The answer is that if the power dissipation of the source decreases
when the reflected power is incident, then destructive interference
energy is being redistributed back toward the load. That destructive
interference energy includes some (or all) of the reflected energy.

The forward wave is associated with EfwdxHfwd power. The reflected
wave is associated with ErefxHref power. The energy in those two waves
traveling in opposite directions at the speed of light in the medium
must be conserved.

For instance, when the load at the end of an ideal 1/4WL feedline is
changed to a short, the forward power is still the same and the
reflected power is equal to the forward power. Yet, the source
dissipation has been reduced to zero even though the reflected power
"is absorbed by the source". In the source resistor, the forward
current is equal in magnitude and 180 degrees out of phase with the
reflected current and the net current superposes to zero. That's the
definition of "total destructive interference" and according to the
conservation of energy principle, the energy involved has to go
somewhere - so it is redistributed in the only possible direction -
back toward the load associated with the "total destructive
interference" that occurs in the 50 ohm source resistor.

The main point to this part of the discussion is to realize that the
forward and reflected wave energy is flowing through the 50 ohm source
resistor because the physical reflection coefficient looking back into
the 50 ohm source from a 50 ohm feedline is zero.

FWIW, I've built audio amplifiers with output transistors with f-sub-t around 50MHz. Those transistors certainly would provide decent power gain at the lower frequency HF ham bands. They were used in the audio amp to achieve very low distortion across the audio spectrum (a very few PPM at full rated power output).

One big difference between (typical) audio amplifiers and (typical) RF power amplifiers is in the use of negative feedback. In an audio amplifier, voltage-derived negative feedback yields a very low amplifier output impedance. In almost all RF power amplifiers, little or no negative feedback is used, so the output impedance is generally much higher than with an audio amplifier running similar power and supply voltage to the output devices.

But again, the source impedance of a transmitter is seldom important in the application of the amplifier. What's important are things like the optimal load impedance and the rated power output. I'd put things like distortion specs for a linear amp far above source impedance in importance. If you (the lurking reader) think source impedance is important, please explain in detail _why_.

Cheers,
Tom

Hello Cecil,

Ever looked at the plate current indicator during tuning? I think you did. Here you see that plate loading affects plate current, hence DC input power to the PA.

Just convert the voltage reflection coefficient (as seen by the PA) to an impedance and work this back through the Pi-filter to the plate. Now you can forget the whole reflected power story.

What happens now depends on what the plate sees. Due to internal feedback (grid capacitances) and/or voltage saturation issues, both plate dissipation and average plate current (so PA input power) may change. Same is valid for solid state PAs also. Changing the load changes device dissipation and DC input power.

I mentioned this in this thread and a similar thread about a year ago.

your question directly: reduction in power dissipation can occur when the impedance as seen from the active devices increases. It will go into voltage saturation, and this leads to a reduction in average (DC) current and integral of V*I product. V can be plate voltage, I can be plate current.

> The answer is that if the power dissipation of the source decreases

If some of the reflected wave re-reflects at the cable-PA transition, you will notice this very likely at the forward power indicator. It also shows that in that case the output impedance of the PA isn't 50 Ohms (as is the case with many PAs).

Fully agree, if the source remains a 50 Ohms source under this massive mismatch.

> Yet, the source
> dissipation has been reduced to zero even though the reflected power
> "is absorbed by the source".

I do generally not agree on this one, please convert your Thevenin source to a Norton source. Though the source doesn't deliver any power to the shorted quarter wave line (as its input impedance is infinite), there is still dissipation in the source.

Practical issue (very related to PAs): when you put your shorted quarter wave line directly to a PA with a type of L match (as is used in low voltage solid state PAs), the L match will "convert" this impedance to a very low value, resulting in an near AC short at the drain or collector. This will greatly increase the power dissipation in the BJT or MOSFET.

> "Halitosis is better than no breath at all.", Don, KE6AJH/SK

For the experimenters:
Make this setup: PA – forward/reflected power indicator – tuner – 50 Ohms load. Have a means to measure the PA input current.

Notice DC input current and forward power when the tuner is not used (bypassed) and don't touch PA settings anymore. Now activate the tuner and show slight mismatch to your PA (with your tuner). Notice the PA

input current and forward power reading. You may need to turn of ALC or other means that automatically change the drive level of the actual power device (valve or semiconductor).

Very likely both PA input current and forward power reading will change. You may do this at various power levels and not the difference.

With kind regards,

Wim

Hi Tom,

An Answer to one of my questions (and by inference two of them)!

The inference is there is NO transition frequency where source Z
becomes trivial/meaningful. Hence, statements alleging correlations
at one end of the spectrum must be observed at the other end.

If this is disputed, we (or at least I) would certainly like to see
what that transition frequency is.

>One big difference between (typical) audio amplifiers and (typical) RF

Well, at the RF finals deck, before the Z transformer, there is slight
to no difference in output impedance. Both are sub-Ohm.

>But again, the source impedance of a transmitter is seldom important
>in the application of the amplifier.

This seems at odds with other writers - if it is an AF amplifier. And
yet none seem to be able to describe the transition frequency for
identical designs (such as yours above, or as close to it as
practicable) where it DOES become important (higher output power, as
if any Ham would snub that advantage if (s)he could snip out the Z
transformer in the rig).

One still unanswered question remains that if a low output Z is so
beneficial to achieving higher output power (a claim that none seem
ready to dispute), then why the step up in Z from the finals deck to
the output connector? I have read an explanation from Wim, but it
fails as an argument for AF where a similar mismatch between source
and load is observed - and yet this mismatch is the greatest quality
for an amplifier since sliced bread.

AF - RF A curious tennis match here where what going over the net in this game is a golf ball in one direction, and a basketball in the other.

>What's important are things like
>the optimal load impedance and the rated power output. I'd put things
>like distortion specs for a linear amp far above source impedance in

>important, please explain in detail _why_.

The self-same NEGATIVE feedback, lacking in retail rigs, would accomplish any form of improvement at the cost of what H.W. Bode called "noise gain." The dollar cost is not inconsequential. Not much more detail is needed for the average Ham.

For the better than average Ham, the increase in NEGATIVE feedback, goes directly to lowering:
Gain,
Power out (as a function of following gain),
Bandwidth (as a function of following gain),
Distortion,
Power supply disturbance,
Noise,
Input Z (or through clever design, raising it),
Output Z (or through clever design, raising it),
while increasing cost in near or GREATER proportion.

Every Ham knows the adage that there is no such thing as a free lunch, and the marketplace enforces that without exception.

Let's see here, a reported source Z as low as 15 (let's just call it 20) Ohms with 100W into 50 Ohms. I have read an explanation that this is impossible (or improbable) for RF from a retail HF rig (such as a TS440), but achievable at AF.

Meanwhile, back at the tennis match....

At the risk of removing a snippet from context, and simplifying in
language and construction:

BELOW a
transition frequency
audio amps source rated at LOW Z sourcing high power into HIGH Z loads
work.

ABOVE that
transition frequency
retail Amateur transmitters source rated at LOW Z sourcing high power
into HIGH Z loads
do not work.

I wonder if that works (sic) with these statements reversed?

Bonus question:

What is the transition frequency?

Both questions can be simply answered: the first with a binary
response, the other with a numerical response (two place precision is
OK - even one place precision is sufficient).

This is the price of subject drift:
"AF amp specs as proof of RF amp performance."
What a work of obscurity.

You can challenge the premise, of course; but to reduce rambling
thoughts driven by subject drift, and to remain on topic:

Hello Richard,

Part from original posting (salmonella):

"Something I haven't seen is a discussion of the source impedance of
the transmitter. My curiosity was piqued today as I took some baby
steps into EZNEC. A particular antenna had such-and-such VSWR if fed
with a 50-ohm cable and a different value if fed with a 75-ohm cable."

The subject is output impedance of a PA. I made a clear statement
regarding this in my first reaction.

Part of your posting:

> Though it's a red herring typical of Ham-speak, most modern retail
> 100W RF transmitters for amateur service have a very low output
> impedance, a fraction of an ohm [editorial: until, of course, it goes
> to the Z transformer that precedes the bandpass filter].

The above text is basically on topic, but not correct, so I suggested
a correction. In my opinion, the push-pull example is OT also.

Some snippet from you posting:

> You can challenge the premise, of course; but to reduce rambling
> thoughts driven by subject drift, and to remain on topic:

Richard, who made that claim regarding that low output Z is so
beneficial? I didn't, so I also did not explain it. I only said that
many PAs don't operate under conjugated match (or even were not
designed to operate under it). This is valid for audio also.

On May 14, 1:56 pm, Wimpie <wimabc...@tetech.nl> wrote:
> Now you can forget the whole reflected power story.

Which is exactly what most people do - just forget the problem and hope it will go away. Some have said just to calculate the voltage/current and the energy (or power) will take care of itself. What this requires is ignorance of the well-known laws of physics from the field of optics. When one understands the laws of physics that effect the boundary conditions for RF waves including the role of interference, all of the component energies can be easily tracked through a system in the same manner the track irradiance through an optical system because they cannot measure the voltages and currents. Method#1 is the way most RF engineers analyze a problem. Method#2 is the way optical physicists are forced to solve the problem.

Method#1: Calculate the voltages and currents and superpose them. (One way is using s-parameter voltage equations.) Calculate power at the end of this process.

Method#2: Calculate the irradiances (power densities) and merge them together using the irradiance equations. The irradiance equations are what one gets when one squares the s-parameter normalized voltage equations.

When you say "forget reflected power", you are asking people to forget the ExH power contained in every EM wave. You are asking people to forget that EM waves must necessarily travel at the speed of light in the medium, i.e. component EM wave energy cannot stand still in standing waves. You are asking people to forget the conservation of energy principle.

Earlier I suggested that we concentrate on a simpler lossless example that doesn't involve the source impedance at all. It doesn't matter what the source impedance is. All that matters is that the source is delivering 70.707 volts to the 50 ohm feedline. Here it is again:

100W--50ohm--+--1/4WL 100ohm--200 ohm load

During steady-state, Pfwd is 100w and Pref is 0 watts on the 50 ohm line. Pfwd is 112.5w and Pref is 12.5w on the 100 ohm line. Exactly what happens at the Z0-match point '+' to reverse the flow of that 12.5w reflected power wave? (There are no RF source or DC supply arguments behind which to hide.) The reflected voltage reflection coefficient at point '+' is -0.3333, i.e. the negative of the forward voltage reflection coefficient at the load.

The ExH power (Poynting vector) in the reflected wave from the load is 12.5 watts. It is necessarily traveling toward the source at the speed of light in the Z0=100 ohm medium. It necessarily contains measurable real-world energy and momentum. Exactly what happens at point '+' to reverse the momentum and energy flow of that reflected EM wave? All the arguments in the world about what happens in the source has not answered that question and this example doesn't involve the source at all.

> I do generally not agree on this one, please convert your Thevenin
> source to a Norton source.

Sorry, that particular source was not my choice but was instead W7EL's choice in his food-for-thought series. He specifically states he is NOT talking about any equivalent circuit but is instead talking about a good approximation to a real-world source with a 50 ohm source resistance.

I do not see how the above energy flow problem/example can be solved without an understanding of the principles of interference (covered in section 4.3 of "Reflections" by Walter Maxwell. If you can adequately answer the questions without any direct or implied reference to interference, you will be the first I know of on ham newsgroups to have done so. Hint: squaring the s-parameter equations yields those interference power terms. If you choose not to respond to this simpler example, I will understand your reasons based on "forgetting reflected power".

Message-ID: <4DD04191.8050309@qrz.com>
Source record: 4920

This is in regards to the thread on qrz.com.

I have started sending this to members of the site. Are you going to address this issue? If not the next step will be the sponsers. I wonder what a capitalistic business will think of the sensorship on an opinion page. I'm not going to stop this campaign untill you reign in your mods. There is no reason that they just up and shut down some of the threads that they shut down. And if a thread is shut down there should be more of an explanation other than, "I don't like it. I can shut it down and I deem it so". Address this issue openly on the board. If not. Let the games begin.

Opinions and Editorials
New Hams

If this is what the MEMBERS of the board want to discuss on the, now read this part twice if you must. "Opinions and Editorials" section of the forum than we will do it regardless of what you say, do or think. These are our OPINIONS on the issues of the day. Whatever that may be. You and the other mods need to grow some rhino skin and just learn to ignore posts that you don't care for and stop being a tin star sheriff who thinks his ass weighs a ton. Build a bridge. Get over it and your self. We all ignore posts that we don't care for. We are adults. Evidently you are incapable of doing so. and don't give me this crap about it being for the greater good of the masses. You sobs sound more and more like our elected officials every day. We will, for the most part self regulate ourselves. I see it as just a power trip for you and the other mods. I do agree in some regulation on the board but on a forum that has the word "OPINION' in it. Come on, lets be real. It will run it's course all on it's own. I speak for more than a few on the board. You think you are way more important than you really are. Open the thread back up and watch what happens. It will get old eventually and revisited occasionally but so what!? It is an OPINION page! Just because you don't care for it is pretty much saying that we are only allowed to post things that suite your opinions. And that sheriff is utter BS. When you lay down in bed tonight think about a purple horse, first that is something that you will never get out of your head and second think about how utterly controlling you are being on a forum titled "Opinion". Think man think! What your doing here is no way to run a board. It is a power thing on your end regardless of how you want to justify it.

It is strongly urged to reconsider the closing of the thread and others that have been closed for reasoning that can only be understood by the mods. I guess you are a little like the Government, You seem to think

that only you know what is good for us. What a bunch of crap.

Go to the site and see for your self. Hammer the point home. Just asking for a little help fellow hams. www.qrz.com

I don't get why you're so hung up on some transition frequency between "RF" and "audio" amplifiers. You're looking at it in the wrong dimension. Think instead of the loads they drive. Speakers (the usual load for audio power amplifiers) work best when driven by a voltage source, so audio amplifiers are designed to look like voltage sources. With antenna systems, it doesn't much matter what the source impedance of the driving amplifier is -- as long as the transmitted bandwidth is small compared with 1/(transmission line time delay) [question to ponder: why would I care about that?] -- so RF amplifiers of the sort we normally use are simply not designed with an eye toward providing any particular output impedance.

You're probably well aware that there are times when I'm personally extremely concerned about providing an RF source that has a well-controlled output impedance (pretty much always 50 ohms, just because of how it's used, but could just as well be 75 ohms, or 100 ohms balanced, or some other specific impedance). That's not the case for the lion's share of ham applications, not even in sources used for simple impedance measurements. There are a few situations in which a ham might legitimately care about transmitter/amplifier output impedance, but they are relatively rare. I'm willing to listen to arguments to the contrary, but have yet to see any convincing ones.

Be careful what you say about the effects of negative feedback added around an amplifier... (That could be a reasonable topic in another group, but not in this thread, and probably not even in this group.)

Cheers,
Tom

Not sure exactly what thread you're referring to, but qrz.com is a not a public forum, it is a privately owned website, so, the owners can do what they want with it.

It is a 100 ohm feedline. The impedance at the + point looking toward
the load is 50 ohms. The 100 W source will see the first 50 ohms and
then the impedance at the + point. The total impedance seen by the
source is therefore 100 ohms. A 100 W source will deliver 100V to this
100 ohm combination and 50V of it will appear at the + point. Where does

the 70.707V come from?

Just think of it this way, in NGs, if you don't like to view something/someones-text, you simply plonk them.

On a private site, if you don't like what someone else says, you can stop everyone else from seeing what they say -- IF you are a moderator. (Moderated NGs serve the same function(s) i.e., you can control what other people say, and who views it.)

Your only error is giving others the right to censor what you see, and then complaining about it! If you don't like it, don't empower them ...

Regards,
JS

Hello Cecil,

I'm rather familiar with S-parameters and unbounded EM phenomena. We are discussing coaxial cables with very small diameter with respect to wavelength, therefore full TEM condition is applicable, even some small distance left or right from a discontinuity. So you can fully replace E cross H by a voltage and current approach (as is used in any vector network analyser).

Regarding impedance, reflection coefficient and interference issues; when you know one of the two (and Z0), you can calculate the other (of course you need to consider phase). All interference issues are accounted for in Z, given a transmission line impedance (Z0).

Transmission line theory is not a goal, but just a means to reach your goal. It is fully acceptable to convert Ref.Coef. to Z (and vice

versa) to efficiently solve your problem. So when you convert an RC to a Z, you can forget all transmission line calculations that you used to find that Z. As Tom mentioned, we are discussing narrow band systems, not wide band transmission systems.

I am not ignoring a problem (as you suggested), I am just using the right tool to solve a problem. I remember from several people, the best Engineer is the one that knows what things he has to take into account and what things he can ignore. You introduced optics here, are you going to introduce QM also to show that I (and some others) are completely wrong w.r.t to PA output impedance?

Cecil, I think you have sufficient knowledge to form an opinion without hiding behind others. You also have the equipment to figure out some things yourself, and I gave some hints to help you. The only question is, are you willing to do this?

With kind regards,

Wim

I said: "All that matters is that the source is delivering 70.707
volts to the 50 ohm feedline." That would be at the source SO-239
terminal to PL-259 50 ohm coax junction. I did *NOT* say there is
70.7v on the Z0=100 ohm feedline. There is indeed 100 volts on the
Z0=100 ohm line.

The source is Z0 matched to 50 ohms and is
delivering 70.707 volts and 1.414 amps to the 50 ohm coax.
70.7/1.414=50 ohms. 70.7*1.414=100 watts.

Here is a better diagram:

http://www.w5dxp.com/enfig1.gif

Pfor1=100w, Pref1=0, Z01=50 ohms, Z02=100 ohms and 1/4WL, Load=200
ohms. Everything except the load is lossless.

I apologize if my one line diagram was confusing. It is extremely
difficult to draw ASCII schematics using a proportional font.

I'm sorry, Wim, that is just not true. When you convert a V/I ratio to a lumped circuit impedance, you are switching models in mid-example and it changes everything in one direction (while keeping conditions the same in the other direction). Switching to a model that doesn't recognize reflections at all when a question about reflections arises is an obvious logical diversion. The lumped-circuit model does not recognize reflected energy and therefore does not allow the tracking of reflected energy. The distributed network/wave reflection model does allow for the tracking of reflected energy and was developed because of the limitations of the lumped circuit model.

I will buy your assertion that one can use voltage and current to achieve the same thing if one is careful not to violate the known laws of EM wave physics. In my example, the reflected power on the 100 ohm line is 12.5 watts. The reflected voltage is 35.35 volts. The reflected current is 0.3535. The reflected voltage and reflected current are 180 degrees out of phase so the power is real, i.e. cos(180)=1.0, and the reflected wave has a Poynting vector magnitude of 12.5 watts (per coax cross-sectional area).

In my very simple example, there is no reflected power on the 50 ohm feedline yet there is (35.35)(0.3535)=12.5 watts of reflected power from the load incident upon the 100/50 ohm impedance discontinuity. I ask you again: Exactly what phenomenon of EM wave physics causes the reflected wave to *reverse* its momentum and direction of energy flow when the magnitude of the reflection coefficient is 0.3333? As long as you refuse to answer this simple question about such a simple example, this discussion will go nowhere.

> Cecil, I think you have sufficient knowledge to form an opinion
> without hiding behind others. You also have the equipment to figure
> out some things yourself, and I gave some hints to help you. The only
> question is, are you willing to do this?

If you cannot answer the simple question about what happens to the reflected energy at a simple passive impedance discontinuity, I am not about to trust your assertions about what happens inside an active source. Trying to introduce a more complicated example while refusing to deal with the very simple example that I provided is an obvious and typical logical diversion. Again, I am not going to cooperate in your attempts at diversions. If you don't know why reflected energy reverses momentum and direction at a passive Z0-match, just say so.

Here's an easier example: Two EM waves superpose in a Z0=100 ohm environment. Each wave is 100 volts at 1 amp = 100 watts. The phase angle on wave1 is +60 degrees and the phase angle on wave2 is -60 degrees. The superposition results in a new wave of 100 volts at 1 amp = 100 watts with a phase angle of zero degrees.

We superposed two 100 watt waves and the result was one 100 watt wave. What happened to the other 100 watts?

Hello Cecil,

I answered a simple question requested several times by Walt (I had to reply to it!). It wasn't my statement but I did it. The solution I gave involved both lumped circuit theory (to calculate the net power) and transmission line theory (to calculate forward and reflected power in a 50 Ohms environment).

Even other people had to help Walt to understand a voltage divider (the 212.1*50 issue). Maybe you can comment whether my simple solution (not involving momentum, Poynting vector or optics) is correct or not. I am familiar with the use (and mis-use by others) of the Poynting vector, but I don't discharge 10 kJ through a mosquito when using a newspaper does the job also.

Regarding reflections:
Does a PA see difference between:

1. 100 Ohms lumped circuit load
2. RC = +0.33333 (for 50 Ohms reference)
3. VSWR = 3 (voltage minimum, for a 300 Ohms reference)

The answer is no, all can be converted to 100 Ohms lumped circuit. What is in between the PA and the actual load is not relevant, what matters (for the PA) is what it sees at its SO239 socket.

If you want this question answered, please open a new thread as it is
not relevant to the original question.

Maybe people will ask you a circuit diagram showing the sources and
the combiner circuitry to enable calculation of the net power
delivered by each source. Otherwise people may consider your problem
as a single incident wave problem (as for these type of steady state
signals you first add complex amplitudes, then calculate powers).

I did respond to Walt's request because it is on topic and I stated
that such thing can happen (without given a numerical example).

Lumped circuit theory presupposes that waves do not exist and that RF energy travels instantaneously, faster than the speed of light. You seem to be ignoring the numerous laws of physics violated by the lumped circuit theory. You also seem to be ignoring the fact that when lumped circuit theory yields different results than the distributed network theory, distributed network theory always wins because it is closer to Maxwell's equations.

I gave an earlier CLC Pi-Network Tuner example that proved the lumped circuit model fails when reflections are present. EZNEC results are nothing alike when using the lumped inductance option vs the helical wire option for an inductance in a standing wave antenna.

> If you want this question answered, please open a new thread as it is
> not relevant to the original question.

Asserting that it is not relevant for the purpose of diversion will not make it go away. If one cannot understand, explain, and solve the simplest passive interference problem, how is one ever going to understand, explain, and solve the multiple levels of interference possible within an active source being invaded by reflected energy? If one cannot add one plus one, one is not likely to be able to add two plus two and something akin to that is what I am seeing here. Until one understands exactly how a Z0-match reverses the direction and momentum of a reflected wave, one will not understand what is happening inside a source with incident reflected energy. What is actually happening in reality is revealed when one sticks with the distributed network/wave reflection theory throughout the analysis. People who whine that such is too difficult have to be satisfied with a certain level of ignorance and inaccuracy.

Okay, so your source really looks like a a 100 W generator with no internal impedance but which feeds a 50 ohm line internally. Since the 200 ohm load appears as 50 ohms when fed with a 100 ohm 1/4WL line, there is a match and all the power appears at the load. In that case I agree with your 70.7 volts since 100 W into 50 ohms will result in that voltage.

But I have no need of reflections. The fact that a 200 ohm load appears as a 50 ohm load at the input of a 1/4WL 100 ohm line takes care of all that for me.

73,
John

Sorry John, you can't cut it without the reflections. They may be invisible to you, but they're there doing the work. The 1/4wl line transformer works only with reflections. If you'll give me your email address I'll send you a graph showing how the reflections perform the matching. The actions of the reflections from either end of the transformer is what performs the matching function. The action of the reflections is as necessary to the function as breathing is to life. Believe it!!!

Walt

There's no argument/discussion about that. The question is: Exactly
what happens at the 50 ohm Z0-match to reverse the direction and
momentum of the reflected wave resulting in no reflections on the 50
ohm line? Hint: it is exactly what happens with non-reflective glass
where the 1/4WL thin-film coating cancels the reflections through
destructive interference. Why not alleviate ignorance by taking
advantage of those well understood facts of EM wave physics from the
field of optics?

Cecil,

It seems that you on purpose remove/ignore things that you don't like, but (you know) are true.

A CLC pi filter doesn't know the difference between:

1. 100 Ohms lumped circuit load
2. RC = +0.33333 (for 50 Ohms reference)
3. VSWR = 3 (voltage minimum, for a 300 Ohms reference)

It seems you don't want to notice that.

That it is convenient to use transmission line theory to calculate the load as seen by a PA when transmission line sections are involved, is OK, I didn't deny that.

That lumped circuit theory has limitations is fully understood. Frequently transmission line effects are modelled using parasitic L and C additions yielding accurate models valid up to GHz frequencies (depending on the size of the component). We are below 30 MHz (for this topic).

Here the experience of the Engineer comes into play: when you can use a lumped circuit model and when you need to use transmission line models (the particle/wave issue is similar)?

A helical inductor of an antenna no longer small w.r.t. wavelength may be better modelled with transmission line theory, but that is OT. Even the L of the CLC filter, you can model with a lumped circuit equivalent with more than sufficient accuracy. This is daily business for manufacturers of inductive components.

Generally, converting results from transmission line models to impedance in combination with lumped circuit theory to calculate the load as seen by the active device, is daily practice. Especially here, as we are dealing with narrow band signals and don't have to model the behavior for harmonics. But for some reason you don't want to see that, and you elevate transmission line theory to a goal.

So again, once you did the conversion to Z, you no longer have to worry about transmission line issues in the load or cabling (including reflection coefficient) when treating your PA's CLC pi filter.

Now speed of light becomes important in a CLC pi filter for a HF PA, when becomes "Gaussian" of importance (and may lose all the readers of this topic)?

With kind regards,

Wim

It is not worth wasting my time to notice since *everyone* already knows that a CLC pi filter is not alive and doesn't have a brain so it must necessarily be dumb as a dead stump. You, OTOH, hopefully being smarter than the average CLC pi filter, should know that the conditions existing within a resistor are different from the conditions existing within an antenna with the same feedpoint impedance. Hint: If you don't know what is in the box, alleviate your ignorance by looking inside the box. If you put on the blinders and refuse to look, then you will make errors like you did earlier while measuring an s11 of zero when it was actually 0.3333.

When the task is to determine the exact delay through the inductor, how the heck can the lumped circuit model tell you that?

Wim, I forgot to note that using your stated methods, W8JI "measured"
a 3ns delay through a 10" long, 2" diameter, 100 turn, 100uh, 80m
mobile loading coil. Doesn't a 4 MHz RF wave traveling the length of a
large 100uH air-core 80m loading coil in 3 ns give you some pause for
reconsidering your methods? Every wonder why computer manufacturers
don't install 100uh coils in series with their computer bus lines to
speed up their computers? :-)

Just via the capacitance to ground (for example a CLC model of an
inductor well below the first self resonance frequency). But when
looking to a PA, there is often an additional capacitance left and
right of the inductor that causes the most of the phase shift. I did
some tesla coiling, so I am aware of the various models for single
layer inductors. You are further drifting away from the main subject
(PA output impedance and what mismatch will do).

Actually, you are further drifting away from basic fundamental EM physics and I am not in the mood to follow you. Since you do not understand the basic fundamentals of EM wave interference, you cannot possibly understand what is going on inside an active source with invading reflected energy. You might as well be arguing that God causes everything because your lack of the understanding of the basic physics of interference causes your concepts to resemble religion more than anything scientific. That's not an ad hominen attack, just an observation based on the technical ignorance of EM wave interference that you have presented here on this newsgroup. Sorry for being so blunt but anyone who chooses to be ignorant, when there is knowledge available, doesn't deserve much respect, IMO.

Since you have failed to answer the simplest of questions about passive circuits, exactly what makes you an expert on active circuits?

Transition time, 1/f?

The point is the poor attempts to build a design argument against one
(RF) with the other (AF). Your response of using RF transistors for
AF application in nearly identical topologies suited the point: there
is NO transition frequency.

>Think instead of the loads they drive. Speakers (the

The length of any source Z thread more than proves your point about its care. Which is to say, few care (there we agree across the population of Hams), and there are those few who are vehement about not caring.

>Be careful what you say about the effects of negative feedback added
>around an amplifier... (That could be a reasonable topic in another
>group, but not in this thread, and probably not even in this group.)

I'm quite careful about the effects of negative feedback added around an amplifier. Dare I say that we can be thankful there are none vehement about not caring about that too?

You are being humble, you've written much more than that.

>This is valid for audio also.

Valid for diesel engine design, I suppose, too. Unfortunately,
introducing distraction to the Subject line brings increasingly
distractive responses.

However, I enjoy distraction and I can wrap it back to topic:

For instance, AF transmitters were used during WWI for (literal,
through the) ground communications. Shall we expand on that history
that IS relevant to Transmitter Output Impedance?

References:
http://www.qsl.net/vk3gjz/EarthComs/Artillery%20LOI.pdf
http://www.qsl.net/vk3gjz/EarthComs/GroundComs.pdf
and more....

I dare say that these links, and more, can return the discussion back
to Source Z matching that is intuitive, uses very real resistance, and
no appeals (at least back then) to reactance.

Cecil,

For Walt I made an exception, but I normally don't do someone's
homework. I also don't spend my time solving non-relevant problems; I
have more interesting quests waiting. If you show up with a relevant
quest, maybe I am willing to dive into it.

I am not calling myself an expert, I just designed some PA's, ranging
from kHz to GHz and from mW to kW, some of them with efficiencies to
over 95%. Together with antenna design and consultancy it assures me
that at the end of each month I have some money left.

With kind regards,

Wim

> If you show up with a relevant
> quest, maybe I am willing to dive into it.

Wim, here is why my questions for you are more than just relevant. It is imperative that someone lecturing us on happenings inside that PA RF volcano be able to understand what is occurring during a passive event involving forward and reflected EM fields and waves occurring at an impedance discontinuity outside of a PA.

Two of the physical quantities that must be conserved are energy and momentum. EM RF fields and waves contain both energy and momentum which must be conserved. I have asked you to tell us exactly what laws of physics govern the reversal of the momentum and direction of energy flow at a Z0-match at a passive impedance discontinuity in a transmission line. You have refused to do so and asserted that such is irrelevant. I contend that I could not have asked a more relevant question - thus the reluctance to provide an answer.

The answer to the question is contained in my energy analysis article at:
http://www.w5dxp.com/energy.htm
A passive Z0-match relies on superposition of waves accompanied by interference effects to explain the reversal of reflected wave energy direction and momentum. Walter Maxwell has called the process a "virtual open-circuit" or a "virtual short". In my article, I explain how it is a two-step process involving normal reflections and interference patterns at the impedance discontinuity. It works exactly like non-reflective glass covering a picture with its 1/4WL thin-film coating where two sets of reflected light waves undergo destructive interference toward the viewer and, honoring the conservation of energy and momentum, reverse their direction and momentum and flow in the opposite direction toward the picture. This is a well-understood phenomenon from sophomore physics 201. Why most RF engineers don't understand this simple physical process involving EM wave interference is beyond belief. Here's the Florida State University web page again:

micro.magnet.fsu.edu/primer/java/scienceopticsu/interference/waveinteractions/index.html

Set the java application for opposite phase and when the result is zero, scroll down to the bottom of the page to find out what happens to the energy components in the two waves that cancel to zero. Those energy components "are redistributed to regions that permit constructive interference" just as they are at a Z0-match in an RF transmission line where there are only two possible directions for RF

energy flow. For every destructive interference event in one direction, there will be an equal magnitude constructive interference event in the opposite direction. At Walt's "virtual short", total destructive interference energy toward the source is redistributed as constructive interference energy back toward the load.

I studied this subject in my EE courses at Texas A&M during the 1950's. The textbook was: "Fields and Waves in Modern Radio", by Ramo and Whinnery, (c) 1944, 1953. The subject is covered under "Quarter-Wave Coating for Eliminating Reflections" in the chapter titled: "Propagation and Reflection of Electromagnetic Waves".

Hello Cecil,

I am familiar with quarter wave (and multi layer) coatings to reduce reflection. I am not waiting for a lecture on (un)bounded wave propagation. If I don't have something present in my mind, I know where to find it.

As mentioned earlier, you can convert all the wave phenomena in the coaxial feed line to impedance as seen by the PA. You are unnecessary complicating things, hence loosing more public that may have interest in this topic.

Maybe you (and other people) should carry out the experiments I suggested in this thread (looking to forward power, net power and DC input power versus small load mismatch [normally referenced to 50 Ohms]).

With kind regards,

Wim

Wim, I'm amazed that you don't find the more-detailed explanation of how impedance matching occurs via wave interference of any value. Many RF engineers have traditionally believed that a PHYSICAL open or short circuit is required to produce a reflection. As a professional antenna engineer with RCA in 1973 I discovered and published the wave mechanics that produces the VIRTUAL open and short circuits that are required for achieving an impedance match. I took bashings from those traditional engineers, who said reflections cannot be engendered by wave interference, until they studied my data more carefully and finally agreed I'm right. Remember, James Clerk Maxwell also had his detractors until they finally saw the light.

Hopefully you realize that if anything of that nature is happening
inside a PA, then your source impedance calculations can be off by
magnitudes.

Hello Walt,

It is not that I don't see the importance of reflections / wave interference, as I use transmission line theory on an almost weekly basis. However one don't need to complicate the matter by using transmission line theory for a HF PA.

When you open your rig, you will very likely not find a >10" long 100uh inductor in the output section of your PA. Also your capacitors have very small size w.r.t. wavelength. A lumped circuit model and a load specified as an impedance is therefore more than good enough to discuss PA complex output impedance and what CAN happen when you apply mismatch.

You can't tell what happens exactly, because then you need to dive into the circuit diagram of the PA to evaluate current and voltage waveforms at the active device.

With kind regards,

Wim

Hello all
I just picked up an old CDE AR22R rotor and controller
It is missing the choke for the pulse switch from the rotor to the
controller
anybody ever have to replace one of these or know the value ??
In the drawing it is labeled CH and part #A52 50426-00
and I cant find anything on it
Thanks in advance to all that read and reply
Howard

I can only quote Einstein (once again) for you:
"Everything should be made as simple as possible, but not simpler."

You have ignored Einstein's advice and "uncomplicated the matter" to the point of violating the laws of physics. When you use the distributed network model for part of the circuit and then switch, mid-stream, to the lumped circuit model, you are indeed violating the laws of physics (as I have pointed out to you before). But you are certainly free to delude yourself into ignoring reality and choosing to commit technical suicide in the process. When you switch to the lumped circuit model, you are presuming faster than light speeds and completely ignoring the existence of EM waves. The fact that an EM/RF signal cannot travel even one inch in zero time simply cannot be ignored. If you take that one inch speed of light delay into account, hopefully you will realize just how technically confused you really are about the magical reversal of cause and effect concepts that you are promoting.

For what it's worth, in my work I design a lot of filters and matching networks. I regularly model the designs before I build them, using the level of detail I feel is appropriate. When I build the physical filter or network I've modeled, I compare the measured response with the response predicted by my model. I do that in some detail. I almost always modify the model as necessary, adding detail so it matches the measured performance. When I say I add detail, I don't mean that I do it haphazardly, but rather that I look closely at the physical realization and add pieces to the model that match pieces of

the physical realization. Because I've gone through this design cycle many times, with many different topologies and for a variety of frequency ranges from below 1MHz to above 1GHz, I have a pretty good idea before I start a new design just what level of detail I'll need.

What I find from this is that, just as Wim says about PA matching networks, I seldom need anything beyond representations of the lumped components when I'm dealing with low frequency filters that don't have high loaded-Q resonators. Up to 30MHz, I don't recall ever having to use transmission lines in my models to get excellent agreement between the model and the physical implementation (except in the rare cases where I've included transmission lines in the physical implementation of a low frequency network, of course). I do often have to add parasitic elements--sometimes even for relatively low frequency filters. (I remember having a technician build a 1MHz filter for me; he couldn't understand why his didn't work anywhere near as well as the first one I had built, until I showed him where he'd allowed other parasitics to creep in--short lengths of wire with currents shared between two high-Q resonators...) I'm _FAR_ more likely to need to include mutual inductance between two coils in a model, than I am to need to include a transmission line.

On the other hand, when I'm dealing with filters above 100MHz, it's not unusual to include transmission line sections and stubs in my models. Above 200MHz or so, the models generally do benefit from including transmission lines. Mind you, there aren't any hard and fast rules; there is no magic transition frequency. But when you've built models that match reality as closely as I commonly do, you learn to just smile blandly at those who tell you that you "must" consider a coil to be a transmission line or you'll be "wrong."

Finally, even when I do include transmission lines in my models, I don't worry in detail about reflections, or about a time-domain analysis of the situation. Just as there's an equivalence between time-domain waveforms and spectral analysis, a frequency sweep of a system (including phase as well as amplitude response) tells me everything I need to know, in the domain I'm already interested in.

I hope Wim (and others?) will excuse the off-topic drift here. And I'm _still_ trying to figure out _why_ anyone would care about the output impedance of a PA of the sort used at HF to drive antennas. Nobody has ever convinced me that it matters at all, except perhaps as academic interest.

Cheers,
Tom

Nobody is questioning the efficacy of design methods. Whatever works,
works. What we are discussing is indeed only of academic interest.
Knowing whether my IC-706 is conjugately matched or not does not
affect its operation at all.

From the time (t0) that a PA first outputs a Zg signal to the time
(t1) that the PA senses its load impedance is NOT zero time. How does
the PA know what its load impedance really is when it is not Zg?
Einstein's spooky action at a distance? No, feedback from the load.

Obviously, the PA receives some sort of feedback in real time. What is
the nature of that feedback? What can it be besides feedback energy
reflected from the load? (not in zero time, but at the speed of
light). In the real world, it takes measurable time for the forward
energy to reach the load and measurable time for the reflected
feedback (if any) to arrive back at the PA. The load seen at the PA
source is always an E/I ratio, i.e. a lossless image impedance that
always experiences a delay if it is not equal to Zg, i.e. it usually
contains reflected energy.

Hello Tom,

Applying Cecil's rules, you and I are bad engineers/designers, as we frequently didn't apply momentum, EcrossH, reflections, full Maxwell Equations, etc.

I know of some of your designs and that from others (they are successful). So something in that statement regarding bad engineers/designers is wrong.

When dealing with fresh from school engineers I frequently encountered bad results or good results, but delivered too late (so aren't good in fact). The last category is mostly caused by using approximations that are way over the top, complicating calculations, slowing down/crashing simulations, etc.

Knowing to apply a suitable approximation/model separates the seasoned from the fresh engineers.

Now the original topic (that was output impedance of HF PAs and using non-50 Ohms coaxial cable) is under a pile of reflections, interferences, momentum, photons, etc, it becomes clear to me whether to apply the words "fresh" or "seasoned" to some of the contributors.

> I hope Wim (and others?) will excuse the off-topic drift here. And
> I'm _still_ trying to figure out _why_ anyone would care about the
> output impedance of a PA of the sort used at HF to drive antennas.

Tom, excuses are not required, I consider your reply as an attempt to get the discussion on-topic again.

Hello Cecil,

You keep on luring us (and others) into non-relevant discussions.
Snippet from your posting to Tom:

> From the time (t0) that a PA first outputs a Zg signal to the time
> (t1) that the PA senses its load impedance is NOT zero time. How does
> the PA know what its load impedance really is when it is not Zg?

> always experiences a delay if it is not equal to Zg, i.e. it usually
> contains reflected energy.

There must be some (for us hidden) reason to do this.

We are discussing near steady state sinusoidal signals, so amplitude
and phase can only vary slowly (if not, other amateurs would not be
happy with you). Especially in case of manual load pulling, it doesn't
matter when there is a back and forth delay of 100 us (that is 10 km
of coaxial cable!!). All such delay actions are fully covered by the
concept of impedance (and steady state transmission line theory). We
are not discussing wide band systems where a reflected signal may be
uncorrelated with the actual output signal.

Cecil, just HOW do you propose to MEASURE the effect you describe, as seen at the transmitter's output port, using only our HF ham transmitter/PA that transmits a signal with a maximum bandwidth of perhaps 10kHz? If it is going to have the dire consequences you suggested a few postings ago, then it must be trivial to measure...unfortunately, I don't see how, and that bugs me, as one who strives to provide accurate, sophisticated measurement technology to engineers.

Perhaps you missed it, but nobody is disagreeing that the mechanism for establishing a load impedance is reflections in the system of lines and lumped loads attached to the PA output. We are simply saying that, for the bandwidth signals involved, you'll be extremely hard-pressed to distinguish between a load consisting of any number of transmission line segments, along with one or many lumped loads

wherever you want along those line segments, and a simple equivalent series RLC.

I suppose it will be lost on most of the lurkers, but it's a bit of a bad joke to deny that one can make valid PA output impedance measurements with a signal very slightly off-frequency (less than 1kHz), and then claim that reflections in a system of maybe a couple hundred feet of coax makes a major difference in how the load behaves as compared with a lumped RLC.

Cheers,
Tom

By the way, what is the impedance of a constant 100W source looking back
into its short piece of internal 50 ohm line?

John

I don't have a proposal and am just pointing out some of the technical problems associated with some of the methods being proposed. FYI, when one uses a model that presupposes faster than light propagation speeds to try to explain something happening in the real world, one should expect some skepticism - unless one can prove that he is using entangled photons. :-)

Hello Cecil,

Could you please explain why the lumped circuit approach used by many people across the world presupposes faster than light propagation (as I can't)?

In my opinion it only presupposes that speed of light is not of importance and if it does, you can model that very easy by adding some additional lumped components in many cases.

Just take a circuit diagram of your rig, lumped components all over the place and if there are coaxial cables, they are just for transporting a signal from one place to another place. Did you ever used a circuit simulator, if so, did you model every capacitor, resistor, etc with a transmission line model?

You may evaluate for yourself a CLC section and see what the output versus input does. Of course you could also put it in some circuit simulator. And again you are trying to introduce non-relevancy into the topic.

All that is required looking into the 50 ohm flat coax is that the
voltage be a constant 70.7 volts. V^2/Z0 is automatically 100 watts.
So the source could have any internal impedance under the sun as long
as it supplies 70.7 volts into 50 ohms. Didn't you say earlier that
source impedance doesn't matter?

http://hamwaves.com/antennas/inductance/corum.pdf

"The failure of any lumped element circuit model to describe the real
world lies at its core inherent *presupposition*: the speed of light
is assumed infinite in the wave equation."

"Lumped element circuit theory assumes that there are no wave
interference phenomena present, that is - the currents entering and
leaving the circuit element's terminals are identical."

http://www.classictesla.com/download/corum_lumped_failure.pdf

"In fact, lumped-element circuit theory inherently employs the
cosmological presupposition that the speed of light is infinite, as
every EE sophomore should know."

"Lumped circuit theory fails because it's a theory whose
presuppositions are inadequate. Every EE in the world was warned of
this in their first sophomore circuits course."

Give me some time and I will compose an example based on EZNEC results
for a lumped inductor vs a helical inductor of equal inductance. The
results are nowhere near the same.

The example is a 4 MHz series circuit with a 100v source, a 72uH
inductance, and a 2570 ohm resistor.

Using a 72uH lumped inductance, the current is the same all around the
circuit and is 0.032 amps at -24 degrees, i.e. the source current is
24 degrees out of phase with the source voltage.

Using a 72uH helical inductance, the source current is 0.039 amps at
-0.02 degrees, i.e. in phase with the source voltage. The load current
is 0.039 amps at -42.4 degrees. The phase shift through the helical
inductor is more than 40 degrees.

As you probably know, the phase angles of superposed waves have a
drastic effect on the resulting impedance.

Hello Cecil,

Can you describe the complete setup, or post a simple drawing
(including ground path, source and load and position of current and
voltmeters). I think that I can model it by using a lumped inductor
with 2 capacitors (in fact a section of an LC delay line). What is the
total wire length (just curious to know)?

72 uH, seems large for a matching inductor in a PA (at say 4 MHz, just
22 pF to resonate).

I'm not speaking for Wim, but I think we are both saying the following:

* You have a known load
* You have a transmission line with known characteristics
* Is is possible to use a Smith chart to get the impedance at the input
to the transmission line.
* We now know the load applied to the transmitter.

All we need to know we get from the chart. We admit that reflections are
responsible for the impedance transformation from load to line input.
But, we don't need to know anything about the reflection details, energy
content of the line, nor how light would like it.

So, we are saying that the load at the line input can be viewed as a lumped circuit. So now we have a transmitter loaded with a lumped circuit for further analysis.

That's all. It's simple.

John

Do you have EZNEC? If so, I can just upload the .EZ files to my web
page.

:-) It's just what I had available - an EZNEC version of a Texas
Bugcatcher 80m loading coil.

It doesn't quite work that well. I gave an earlier example where Wim got the the s11 parameter wrong by an infinite percentage. The s-parameter equations for a lumped circuit vs an impedance discontinuity are nothing alike. Even the IEEE definitions for the two different types of impedances are different. The interference conditions at the impedance discontinuity can be proven to be different than for the lumped circuit replacement.

> That's all. It's simple.

Quoting Einstein again: "Everything should be made as simple as possible, but no simpler." :-)

When you switch to the lumped-circuit model, you are agreeing to faster than light signal speeds, NO superposition of signals, zero interference, zero phase shifts through coils, identical current everywhere, etc. How the heck can you assert and prove there is zero interference inside a source when reflected energy is flowing through it?

Exactly so, John. Good summary. So long as the transmitter's bandwidth is small enough that you are always operating practically at steady-state conditions, the transmitter can't tell the difference between whatever assembly of transmission lines and lumped loads distributed along those lines you want, and a simple lumped circuit that presents the same impedance as the steady-state value of the jumble of transmission lines out there. (For very narrow-band loads, you might want to use a lumped equivalent that presents sensibly the same impedance as the load across the whole transmitted bandwidth, not just at one point.)

It is NOT that anyone is assuming "faster than speed of light," it's that we're recognizing that the (HF voice-bandwidth) transmitter is slower than molasses relative to the propagation times involved in a couple hundred feet of coax, or probably even a couple thousand feet. The attenuation per foot of the lines we use is high enough that it's just about impossible to deviate significantly from steady-state conditions for the bandwidths we use.

That's certainly not true for pulsed radar signals, or for fast-scan TV, or for other wideband signals. In those cases, you'll probably find it pays to insure the line is matched to the load so there aren't

significant reflections, and you may want to arrange the source (PA/ transmitter) to have an output impedance close to the line impedance so it absorbs any reflections that do happen at the load end of the line. (If you want to get fancy, you might use a circulator to insure dissipation of such returning signals.)

Cheers,
Tom

The Smith Chart is a tool - a blank graph. How could it be wrong?
Like any tool, it has limitations and can be abused.

On May 19, 4:05 am, Wimpie <wimabc...@tetech.nl> wrote:
> Would you please remind me to the example where I was completely wrong
> with S11?

----50 ohm--+--1/4WL Z0=100--200 ohm load

s11 is 0.3333 at point '+'. Put it in a box and s11 magically becomes
0.0?

The first s11 is a physical reflection coefficient, the second s11 is
a virtual reflection coefficient. The virtual 50 ohm impedance is
lossless. All the power is dissipated in the 200 ohm resistor at a
reflection coefficient of 0.3333.

> Did you ever DESIGNED some serious electronic hardware?

No, but being a good designer has nothing to do with the present
academic exercise. W8JI is a good designer yet concepts like yours led
him to "measure" a 3 ns delay through a 100 uH air-core 80m loading
coil when the actual delay time is closer to 21.5 ns. That's what
happens when one relies on the lumped-circuit model and ignores
reflected energy. The relative phase of a standing wave doesn't change
with length which gives the illusion that the signal is traveling
faster than the speed of light, i.e. zero phase delay.

I will turn the coil example into a brainteaser and post it to my web
page.

Hello Cecil,

Your circuit (lumped inductance example) with 100V input into 72uH
with 2570 Ohms load):

From lumped circuit simulation (Beige Bag PSPICE, version 4
professional):

I_source = 32mA, -35 degrees
I_load = 32mA, -35 degrees

This agrees with hand calculation, all phase with respect to input
voltage.

From simulation, but now a pi filter C=6pF, L=72u, C=6pF, load = 2570
Ohms
Simulation carried out with same PSPICE package without using
transmission line sections:

I_source = 38mA, -1.5 degrees
I_load = 38mA, -44 degrees.

Total required time for setting up the simulations and guessing the
parasitic components to simulate the actual inductor behavior: about
15 minutes.

As you can see good agreement without using any of the photons, speed
of light, momentum and other issues, just lumped circuit simulation
where some parasitics are added. Of course a can make a better match,
but this doesn't contribute to the discussion.

I hope that some followers or contributors will do the same simulation
in a lumped circuit simulator, so that we don't arrive in a discussion
that I am cheating.

Cecil,

It is very simple, the 1/4 lamba line (100 Ohms) looks into a 200 Ohms load, so seen from that line, VSWR = 2, hence resulting in RC=0.3333.

The 50 Ohms source looks into a 50 Ohms load (you can use the quarter wave formula). This equals VSWR=1, so RC=0. I think I wasn't wrong! As mentioned before, a source (whether PA or small signal) doesn't see the difference between a lumped 50 Ohms load or your quarter wave line with 200 Ohms load. Whether or not it is "physical" or "virtual" is also not relevant, just the complex V/I ratio (we call that impedance) counts.

The RC inside the line is of no relevance for the PA.

It may be of importance w.r.t. selecting the right model to solve technical problems. A good example what can happen when selecting

over-the-top approaches is this thread.

Hello Cecil,

I would like to return back to the topic with a brainteaser also. You posted links to some document written by Walt. The first reference (QEX, May-June 2001, http://www.w2du.com/QEXMayJun01.pdf) shows some measuring results using load pulling in table one.

I have a source 100Vp, 4 MHz, sinusoidal, in series with a capacitance of 796 pF (that is a capacitive reactance of 50 Ohms). Would you be so kind to determine the output impedance of this source using load pulling (for example using 51.2 Ohms and 44.6 Ohms). Of course I have no problems if you (or somebody else) use a simulator to save time.

If you (or somebody else) feel uncomfortable with a zero ohm voltage source, you may add 1 Ohms in series with the capacitor.

Did you (or somebody else) expect the calculated result based on load pulling?

With kind regards,

Wim

In that case I have no need of S11 or reflections or light. I only need to know that the Smith chart tells me that a 200 ohm load looks like a 50 ohm load through a 1/4WL-100 ohm line. I made it as simple as possible but no simpler.

John

You just proved one of my points. Inventing impedors that do not exist in reality in order to rationalize the real-world delay through a real-world loading coil is exactly what I have been complaining about. Are the imaginary lumped-circuit capacitors, to which you are forced to resort, part of the actual impedance in reality or a figment of your imagination?

http://hamwaves.com/antennas/inductance/corum.pdf
"The concept of coil 'self-capacitance' is an attempt to circumvent transmission line effects on small coils when the current distribution begins to depart from its DC behavior." About the capacitors you added above it says: "Of course, this is merely a statistical determination appropriate for computations ... and *not at all a physical quantity*."

The reason that the source voltage and source current are in phase in the example is because the load resistor equals the Z0 of the coil which is functioning in transmission line mode with a VF = 0.019, i.e. like a transmission line, it is indeed 0.1167 wavelengths long electrically. I have verified such (within a certain degree of accuracy) through bench experiments.

:-) I saw a similar example over a half-century ago - a zero ohm
source that is 100% efficient no matter what the load. A conjugate
match provides enough power to destroy the universe. Question is: If a
source impedance is a pure reactance, can it deliver any power?

Well there you go - my point exactly - it "looks like" but appearances
can be deceiving. You and I know that they are not identical because
we are smarter than the average bear and the IEEE has different
definitions for those two radically different kinds of impedances. We
know that it is a virtual image of 50 ohms because no 50 ohm resistor
exists in reality and no zero reflection coefficient exists in
reality. In mathematical terms, there is no one to one correspondence
between a 50 ohm dummy load and a 50 ohm antenna.

Cecil,

Just solve this source brainteaser (that contains the capacitor) with
the principles outlined in a reference provided by you. Efficiency is
not of importance here, so please don't lure us into new non-relevant
issues.

Though its seems just theoretically, I source providing 100W at 4 MHz
with Zout is = 1 ohm (or less) can be made with today's components.

First I'll point out that the model Wim used doesn't match "the concept of coil self-capacitance," so it's not clear that the rest of what you wrote is relevant.

Now, what do you do about your coils when you discover that they do NOT behave like a TEM transmission line? Indeed they do not; it's pretty easy to verify from measurements on real coils and real circuits. It seems like now you are stuck, because you (seem to) have a lot of trouble looking at a circuit and understanding what's really important and what isn't, with regard to performance in a particular application. Sometimes it's appropriate to use a model that goes well beyond a simple transmission line model of a coil; sometimes the simple transmission line model is far more complex than you need. See Wim's previous posting about the value of understanding that.

FWIW, I understand perfectly well where the capacitances Wim put into his model come from. I know exactly how I would estimate them from a particular physical configuration, and I suppose Wim does something very similar to what I would. They come very much from the real physical world, not from our imaginations.

Cheers,
Tom

Cecil,

Lumped circuit approach gives a good solution for your brainteaser
(maybe against your expectations or hope). It is just distributed
capacitance to ground that can be concentrated into 1 or more
capacitors if you are well below the first resonance frequency.

In a real application when using a lumped 72uH inductor for
calculations, one will find out that the capacitors for a certain
application (for example pi-filter section) have to be somewhat
smaller then based on the lumped circuit calculation.

Regarding transmission line behavior
It is the reason to mention "without using transmission line
sections". Because my PSPICE package also allows use of transmission

lines, if convenient I use them. Do you know how I made my first guess for the capacitors? Just by using transmission line theory. BTW, what is the wire length of the inductor in your HF rig (for 4 MHz band)? It is very likely well below the length for the bugcatcher example.

Did you know that many delay lines were/are made by using multiple CLC sections (for example used in oscilloscopes)?

Again, look to the circuits of your rig, do you really think that the design is carried out by modelling each component as a transmission line. The answer is no (for sure).

We have various religions around the globe; I think we don't need another one based on transmission lines! Maybe for you it was wonderful to explore transmission line theory, but for RF Engineers/ Designers (antenna designers included), it is just one of their means to get the job done.

Maximum power transfer occurs when the load is the conjugate of the
source impedance. Of course, in this case, when the source is purely
reactive, no power transfer is possible with a conjugate match. I
don't think our models were designed to handle magical situations so
I'm assuming this exercise is designed to waste my time (of which I
have precious little left). Come to think of it, didn't you call my
examples, "off topic", and refuse to have anything to do with them?

And, I find the lack of stray capacitance in Cecil's model much harder
to believe than the presence of them in Wim's model.

John

Well, Cecil, we've now reached the end. No resistor exists in reality so
no transmitters, waves, light, transmission lines exists in reality.
There is no one to one correspondence between you and sanity.

This is just plain stupid. You only want to argue.

John

> This is just plain stupid.

I agree. Your above posting is just plain stupid. You are stating the opposite of what I have said hoping some readers will not notice. Resistors exist *in reality* e.g. in dummy loads. You are promoting E/I ratios, existing as virtual resistances, to be as real as a physical resistor. Hopefully, no one ever loads his virtual gun with one of those virtual resistances and fires it at you. Question is, would you die or not? It has been said that everyone creates his own reality and it must be true. You guys have created models of reality in your minds that bear very little resemblance to the real world.

In the field of optics, an real image that actually exists in reality is clearly differentiated from a virtual image which is an illusion that doesn't actually exist where it appears to exist. Light waves are EM waves. RF waves are EM waves. You guys are promoting a model that considers virtual images to actually exist at the point where they appear to exist but are only an illusion. I agree with you - that is just plain stupid.

To summarize: Resistors, capacitors, and inductors, defined under the concept of impedors (from "The IEEE Dictionary") are real-world devices with a physical existence - one can pick them up and touch them.

E/I ratios, containing resistance plus capacitive or inductive reactance, are impedances that do not have a physical existence. Their existence is conceptual and exists only in human minds capable of concepts (much like the concept of God).

When you are standing four feet from a mirror and your image appears four feet behind the mirror, you are arguing that you can replace your actual self with an alternate self four feet behind the mirror and everything will be exactly the same. I agree with you - that is just plain stupid.

Actually, what I am attempting to do is discourage your lumped-circuit
religion, where a 100 uH, 10" long coil, can propagate an RF signal in
3 ns, and move you guys closer to the reality of Maxwell's equations.

> 73, Cecil, w5dxp.com

Cecil,

I already expected that you wouldn't solve my brainteaser (so I did it
in advance), Here is the result for the 100V, 4 MHz sinusoidal source

in series with 796pF, load pulling with 51.2 Ohms and 44.6 Ohms:

V_out (51.2 Ohms) = 71.5V, I_out = 1.396A
V_out (44.6 Ohms) = 66.5V, I_out = 1.491A

Delta_V = 5.0V, Delta_I = 0.095A,

Hence Rout = 52.6 Ohms.

Power into 50 Ohms = 50W.

¡Really strange!, that a fully imaginary output impedance of -j50 Ohms results in real 52.6 Ohms output impedance based on the scalar load pulling referenced by you.

I also applied complex load pulling (that is taking phase change into account) and Tom's off-carrier injection method to the same source. Both methods put out Zout = -j50 Ohms (yes, the correct value).

You are criticizing Tom's method without any solid foundation, but you referenced to a method with very limited application as shown in this simple example.

You are mixing coherent signal theory with non-coherent signal theory (narrow band RF versus unspecified optical), also your reply above has no relevance to PA's for HF amateur service.

Cecil, we have all our specialities and limitations. It is becoming clear that you lack experience in the field of signal processing and RF (systems) Engineering. This is no problem, because many people can live without it. Instead of continuing the way you do, you can better try to grab some of the concepts offered by others. I am sure it will give you better insight in what happens in RF systems, in considerably less time.

Hello Cecil,

I am not addicted to "lumped circuits", I just use the appropriate
model. Many amateurs built and / or designed their own HF PA (and
other circuitry relevant to the hobby). Do you really think that they
all considered every component to be a transmission line?

Transmission lines in general.
I agree with Tom, "Transmission line approach" is also just a model
with limited validity. It all depends on the Engineer/Designer whether
to use it or misuse it.

John, I have always had great respect for VK1OD, but in the URL you presented above I must take Dave to task for asserting that Cecil's concept is suspect, simply because he didn't include attenuation in the analysis of the lines.

Correct me if I'm wrong, but seems to me that a competent engineer begins an analysis assuming lines and components are lossless. Then, if the losses are going to be significant, he factors in the effects of attenuation. If the losses are insignificant he ignores them.

In Cecil's paper he is not ignoring attenuation because he doesn't understand its significance, he is ignoring it only because in beginning the analysis it isn't significant. Cecil doesn't deserve that unfortunate treatment.

Wim, in your calculation of PA output resistance via load pull, you state:

"...load pulling with 51.2 Ohms and 44.6 Ohms:
V_out (51.2 Ohms) = 71.5V, I_out = 1.396A
V_out (44.6 Ohms) = 66.5V, I_out = 1.491A
Delta_V = 5.0V, Delta_I = 0.095A,
Hence Rout = 52.6 Ohms."

The following is what I obtained through actual measurement via load pull:

Vout (51.2 ohms = 76.9v, Iout = 1.502a
Vout (44.6 ohms) = 71.6v, Iout = 1.605a
Delta V 5.3v, Delta I = 0.1034a
Hence Rout = 51.2 ohms

Wouldn't you agree that my measurement method and procedure are pretty well on track?

Walt

Hello Walt,

If you would read again my posting (you removed my source description), I didn't refer to your actual measurements, but referred to your measurement method applied to my source example (my source example is 100Vp in series with -j50 Ohm).

I hope this makes clear the differences.

You apparently have not comprehended what I am trying to say. When one is designing a piece of equipment, whatever works, works. Please don't confuse design/analysis techniques and rule-of-thumb shortcuts with the underlying principles supporting the laws of physics. Enumerating all the design techniques in the world does not tell us anything about what is happening in reality to those photonic fields and waves that necessarily must obey the laws of physics.

Even DC impulses travel at the speed of light. Electron drift velocity is much, much slower than the speed of light. Everything EM is photonic in nature. Photons must obey the laws of physics known to exist for photons. There is simply no getting around that fact. All of the magical thinking, hand-waving, design/analysis shortcuts, and rules-of-thumb in the world are not going to change those facts of physics.

If you do not understand those physical limitations (including. the difference between the two IEEE definitions of impedance) you will never understand what is actually happening in reality inside (or outside of) an RF source. I don't know what else to say.

Hello Cecil,

When one knows the physics well, one knows what to take into account
and what to left out, just to finish the job efficiently. It seems you
don't understand that principle. Is this some lack of understanding
physics?

Do you really believe that when designing an optical detector
(completely off-topic) I don't bother about noise due to quantisation?

> If you do not understand those physical limitations (including. the

Regarding PA's and IEEE definitions, I don't get paid for my
knowledge (if present?), but just for delivering what has been
agreed.

You introduced photons here; I think you may also introduce thermodynamics of electrons as that may be of more importance at our frequencies. I do not violate agreed laws of physics, but only leave out higher order effects that are insignificant in my opinion.

Again, just getting the "job" done is completely irrelevant. This was
an unsuccessful quest for knowledge and understanding of the nature of
an RF source - so I will say, "73", Cecil, w5dxp.com

Here:
JOB = finding a satisfying answer to the thoughts laid down by
Salmonella.

Understanding the nature of an RF source, can be mastered very
efficiently without: photons, momentum, extensive transmission line
theory, Poynting vector, etc. You may visit VK1OD's website
(www.vk1od.net) for ways how to explain things.

:-) :-) :-) And that's exactly how we get 3ns delays through foot long
75m loading coils, EM wave energy that stands perfectly still in
standing waves, and reflected waves somehow existing devoid of any
energy at all.

Beyond just understanding what parts of the physics theory are important in a particular situation, there's the more general concept of compartmentalizing things. The original question was about transmitter output impedance, and to answer that question, you really don't have to get into interminable discussions about what goes on in some arbitrary load. The only things that matter with respect to the load are the voltage, current and phase between them at the output port of the source.

A perfectly valid reason to talk about the load -- what you connect to the source output port -- is how you can configure that load to establish a variety of load conditions so that you can see how the source behaves, and from that, derive the source impedance. In fact, some months past now, Wim and I had some email exchanges about that. The emails were very valuable to me, because they got me thinking about various arrangements of the equipment I have to enable accurate measurements, and brought up points about things that go on _inside_ a typical RF power amplifier that can cause you to measure things inaccurately. For example, an ALC loop with a relatively slow response time could make you think that the amplifier output impedance is quite low if you take measurements more slowly than the response time of the ALC loop. You might even decide that it makes sense to talk about amplifier output impedance as a function of frequency offset relative to the output frequency (or some similar way to talk about the "time response" of the output impedance). It all depends on what you want to _do_ with your output impedance number once you have it, and that's something I don't recall seeing much of in this thread, nor in any of the many previous threads covering the same old ground.

Cheers,
Tom

I have made a tutorial using flash programs that will help you
understand how quadrature modulation and quadrature demodulation
works. It is located here:

http://www.fourier-series.com/IQMod/index.html

I try to show you without getting bogged down in the math. The hope
is that after going through the tutorial that the math will be easier
to understand. (The math for this stuff can be found many places
online)

I'm living in a wooded area and am trying to hit our club repeater reliably. It's cloudy now so I'm and getting a bit of ducting but I have a lot of trees, mostly poplars, in the direct path. I would have a line of sight if not for the trees as I'm up enough in altitude. I can cut the trees, they're mine, but finding the right ones is difficult and i don't want to waste the whole grove.

I go from keying the repeater with no intelligible signal to not being able to hit it. Today I actually have an S meter reading due to the clouds. I am currently using a J-pole and will put up a Yagi soon but wonder if NVIS would work on 2m? I have only seen references to it being applied in HF.

Wait for winter and use a beam antenna to locate the tree(s) that need to be trimmed.

If a 10 element beam won't "blast" through the trees in the summer, it should get you down to a line of 1 or two trees that need to be cut.

A more radio oriented project would be to put a 6m or 10m input on the repeater. 10m should groundwave over the trees anyway. It's easy enough to test.

10m inputs are IMHO neat, at the top of the sunspot cycle, they give your repeater worldwide input. At that point a 10m output would be good too, but for now, it's not much of a problem.

Geoff.

Hello,

The repeater antenna will probably have most of its radiation in the
horizontal plane and 145 MHz is far above the critical frequency, so
your rays will leave earth.

Did you monitor the signal for several time (also winter and rain) to
assess the real influence of the trees? Do you have any possibility to
move the J-pole to another place?

As you can open the repeater now and then, some 10 dB additional gain
will certainly help you to get above the FM-knee (assuming that you
can get the beam at same height as the J-pole. Nice thing is, it will
also improve reception.

With kind regards,

Wim

I can't see that NVIS has any VHF backers.

Can you exploit Google Maps, satellite view, to establish a precise
line bearing from your antenna to the repeater site? If you need even
more help than you get from your new yagi, then such a line bearing
will help identify your "trouble trees."

I had to do it for a new FD site a few years ago. We're in San Diego
and I wanted to work 2m into Los Angeles. First, I used a protractor
to determine LA was X-degrees True (whatever it was) from us; next, on
a close-up print of the FD site, I plotted that same line bearing from
the antenna site to obvious local landmarks which we then used on the
the ground for pointing the 2m beam.

This is not the only approach, but it got me what I needed.

Your yagi may fix your problem completely. Other things to consider:

* Try moving your existing antenna. Even a small movement may cure the problem as you may have cancelling reflections at times. There is almost always a "sweet spot" somewhere in the vicinity.

* Try tilting your antenna to 45 degrees and see if that helps. It might improve reception due to the random polarization of the incoming signal caused by the trees.

Note: do this on a day when the signal is either weak or non-existent. You can always apologize for kerchunking. Or, use your S-meter if you have one.

Cheers & Good Luck,
John

Addendum: If you can add even a foot or two your antenna height, it may
make a world of difference.

Cheers,

I live in a dense mostly redwood forest. Signals vary from full
quieting to not copyable. We also have two co-channel repeaters
sharing the frequency, that also vary radically in strength. I can
often point my 5 element 2m beam in a totally insane direction, and
improve the signal.

>I go from keying the repeater with no intelligible signal to not being
>able to hit it. Today I actually have an S meter reading due to the

I just love technical posting with no numbers. It would be helpful if
you would offer a clue as to the distance you're trying to cover, what
manner of impervious to RF dirt is along the line of sight, antenna at
the repeater, power levels, etc. For extra credit, if you disclose
these plus your exact location, the repeater's exact location, and I
will contrive a Radio-Mobile path profile from you to the repeater.
That should give you a clue as to what challenges you are facing.
<http://www.cplus.org/rmw/english1.html>
It will look something like this:
<http://802.11junk.com/jeffl/coverage/RST/RST-KCRA.jpg>

As for a seat-of-the-pants guess as to a solution, I don't like J-pole
antennas. Actually, the antenna is fine, but the way most people
build, tune, and position them, is what I find disgusting. The lack
of any commercially manufactured J-pole antennas (other than the
American Legion J-poles) should offer a clue. Plenty of plans:
<http://www.google.com/search?q=j-pole+antenna&hl=en&prmd=ivns&tbm=isch>
but nothing from a commercial antenna manufactory.

In my never humble opinion, if you can barely talk to the repeater
with a J-pole, then a yagi will offer a substantial improvement. The
problem is how much gain is going to be needed to make it reliable. My
guess(tm) is that the J-pole has a gain of about 2.5dBi (opinions vary
on the gain), and that you'll need about 5dB more gain to get a decent
link. That means you'll need a yagi with about 7.5dBi of gain. That
can be done with a 5 element 2m yagi. Obviously, more gain is better
as is more altitude.

Good luck.

I beg to differ. I have about 30 years experience in dealing with
propogation through a dense redwood forest (Ben Lomond CA). The trees
in my area are about 120ft high. While moving the antenna around may
temporarily improve the signal quality by reducing frequency selective
fading, multipath, reflections, and just plain bad luck, they do not
tend to remain improved. Trees grow and move around. What works well
now, will probably not work well tomorrow.

I gave up on fixed antenna mounts for my rooftop verticals. (Well, I
have one mounted on a tripod, but that was before I realized what was
happening). Most of my verticals are mounted on 2x12 planks, held
down to the roof with sand bags, concrete blocks, and buckets full of
water. Every few months, I move the antennas around to see if I can
improve the signals to specific repeaters.

>* Try tilting your antenna to 45 degrees and see if that helps. It might
>improve reception due to the random polarization of the incoming signal
>caused by the trees.

I beg to differ again. Tree trunks are mostly water and do an
impressive job of simulating a slot type polarization filter at 2m and
440Mhz frequencies. Leaves and branches will pass RF fairly well, but
not tree trunks. I've played with both polarizations, circular
polarization:
<http://802.11junk.com/jeffl/circular-polarization/>
and some diversity reception. Empirically, signals are about 6dB
stronger going through the trees vertically polarized, than
horizontal. The effect continues up to at least 2.4GHz. Above that,
at 5.7GHz, the signals seem to be going through the holes between the
leaves.

I must admit that I haven't actually tried 45 degrees on 2m or 440Mhz,
but I don't think it will help much. Still, it's an easy thing to
try.

>Note: do this on a day when the signal is either weak or non-existent.

Do it on a windy day, when the trees are moving around, so you can see
how much it will change.

You may be right, Jeff. But he may not have 120ft redwoods around and,
after all, this is a temporary fix until his yagi comes in.

You spent more words debunking the suggestion than admitting that you don't really know whether it could help or not. Good move. And, by the way, I have experience to the contrary at both 144 and 444 MHz. It all depends on the location of the source and the receiver. At 2 meters, some rotation of the antenna can sometimes be helpful. Note that we are not concerned with GHz.

30 years of trying to maintain a stable signal to several distant
repeaters is sufficient to convince me. Trees move and grow, causing
signals to change.

Also, temporary is a rather useless term. In my experience, if it
works, it's permanent.

>Good for you! Pat yourself on the back.

Thank you for the traditional contentious remark.

>You spent more words debunking the suggestion than admitting that you
>don't really know whether it could help or not.

True. I spent more words explaining why I suspect it will not work,
what I expect will happen, and a bit of substantiation. I consider
this a substantial improvement over the traditional one-line
pontification.

>Good move. And, by the
>way, I have experience to the contrary at both 144 and 444 MHz. It all

>some rotation of the antenna can sometimes be helpful.

Perhaps it would be helpful if you read what I had written. I said
that rotating the antenna might help temporarily, but that movements
of the trees, tree growth, swaying branches in the wind, and possibly
sources of reflections, will soon negate any temporary benefits. If
the yagi is going to arrive shortly, then tilting the antenna is
probably a useful exercise.

> Note that we are not concerned with GHz.

Topic drift follows:
Since you mentioned GHz, one of the other problems with living in the
deep dark forest is that DBS satellite dish reception is a problem. I
hacked an 8ft diameter hole in the tree canopy by lopping off some
branches at about the 80ft level, through which I point my DirecTV
dish. Every year, the trees grow a little, requiring that I move the
dish around my roof. During the twice annual solar satellite outage:
<http://en.wikipedia.org/wiki/Sun_outage>
Twice a year, I photograph the sunlight shining through the hole and

onto the dish and roof. If there are shadows of branches on the dish,
I move it to a better location.
<http://www.11junk.com/jeffl/pics/DBS/>
Note the shadow at 12 o'clock on the dish.

If you have line of sight to the repeater I find it hard to believe that
a few trees will cause you problems at 2m.

NVIS will not work at vhf it is an HF mode. 2m signals go straight
through the atmosphere they are not reflected back down.

You don't say how far away the trees are, but if they *really are* the
cause of you problems, if they are at any distance then they will
probably all have to go to give any sort of Fresnel zone clearance at 2m.

A simple map and compass will give you the bearing to the repeater, but
perhaps you would be better off running a propagation prediction program
such as Radiomobile to see if it is actually the terrain rather than the
trees that are the problem.

Ummm... I don't think the yagi is on order.
<http://www.k7jep.org/node/107>

#Begin speculation();

His area has a variety of repeaters available:
<http://www.k7jep.org/node/107>
I would guess(tm) N7JCT 145.230 on Schweitzer Mtn. Idaho.
<http://www.repeaterbook.com/beta/repeaters/details.php?ID=64&state_id=16>
Plugging the coordinates 48.367500 -116.628326 into Google Earth gives
me a view of the area. It seems to be in the middle of a ski resort,
that has been cleared of most trees and is full of trails. Plenty of
trees both up and down the slope, but not around the probable location
of the repeater. I can't identify the trees from the photo, but my
guess(tm) is Lodgepole Pine at about 60ft. The location is not at the
top of the hill and also has hills shading the view for about 270
degrees. I don't think this is going to be a foliage penetration
issue.

KML file for Google Earth:
<http://802.11junk.com/jeffl/kml/N7JCT possible location.kml>
JPG for those without Google Earth:
<http://802.11junk.com/jeffl/kml/N7JCT possible location.jpg>

Blundering forward, N6SXR is shown as getting his snail mail in
Sandpoint ID a distance of about 7 miles. However, there's quite a
bit of dirt in the way, which will be a problem.
<http://802.11junk.com/jeffl/kml/N6SXR to N6JCT.jpg>

At 7 miles, it should be possible on VHF, even with 450ft of dirt in
the way. My guess(tm) is that there's something wrong with the home
made J-pole, coax, radio, or all the aformentioned.

Again, this is a guess(tm) of both the repeater and it's location and
just might be totally wrong.

#End speculation();

>Now you are just being argumentative.

Not really. Methinks that you're being overly defensive. My litmus
test is "duz it answer the OP's question"? If not, you're wasting
your bytes. By asking for help with the design and contruction of a
yagi, it appears that the author is planning to build his own yagi. I
haven't seen any mention of a structure, pole, or tower, so that will
also need to be constructed. Perhaps also a rotator. Methinks
temporary might be a long time.

>I never said it was on order. The
>OP said he was planning to put one up. Therefore, it will most likely

For this kind of thing "RadioMobile" from VE2DBE is the application of
choice. It will load the SRTM terrain DEMs, etc. and plot out the path
quite nicely.
http://www.cplus.org/rmw/english1.html

But, if you can get in sometimes, but not others, the next question is,
"can you hear it"?

How long is your coax?
If more than 20 ft, are you running a preamp?

Getting 10-15 dB gain over a jpole would be easy with a moderate length Yagi. A M2 2M4 (4 elements, $115) is about 10dBi. A 2M9($240) is about 14dBi

1234. A3S with 40 meter add on kit

Does the 40 meter addition change the 20 meter reflector beam to the center beam and the reflector
beam to 15 meters?

I am assuming the A3S by itself works as the shortest beam is 10 meters the 15 meter beam is the
middle and the 20 meter as the longest?

TIA

Hello,

As you can see from the replies, we are in the speculation phase. If
you would like to receive more specialized feedback, you should
provide us with more details about the path, antenna height, nearby
obstacles, vegetation in between, etc (maybe some pictures).

As we are discussing 2 m wavelength, obstacles that may be optically
in the path may introduce less attenuation then expected, but
obstacles that are outside the optical path can still introduce
attenuation.

At 10m (33ft) from your antenna, the first Fresnel zone is about 9m
(30 ft) wide. In addition, the tree attenuation at these frequencies
is not that high. I think of 0.15 dB/m (I hope somebody can confirm
this). It can be less due to diffraction (bending) of the waves around
and over the trees.

I am almost sure, removing some poplar treetops at 10m from your
antenna or more will not change the situation from marginal to good
(because of the relative low attenuation).

Just to be curious, what type of poplar do you have at your site.

With kind regards,

Wim

This is the repeater I am trying to access, 146.780, K7JEP. I have been playing with Google Earth and getting coordinates so I can go over to my neighbors property and stand on the ridge between our properties and see if I can see the repeater and my house. Hopefully that will help me locate the suspect trees.

Addresses here are not all they seem. My physical address is 14 miles
north even though the postal idiots label it in Sandpoint. Approx
location... lat 48.494070 lon -116.447788. You'll see my crazy driveway
and the house. The J-pole sits about 30' above the house. Plenty of
trees in sight.

The repeater, 146.780, in on Gold Mtn., 48.219713, -116.482883 I do not know the specs of the repeater. I am at 48.494070, -116.447788, at 2300' using an American Legion J-pole. It has worked very well in the past but this is the first time it has been up in 15 years. It hits the 145.230 repeater on Schweitzer 59. I'm running a Kenwood 721 at 25 watts trying to hit the 780 repeater. Schweitzer can be hit at 5 watts no problem.

According to his lat/lon numbers, he is 19 miles from the repeater and its bearing is 185 degrees (ref true north) from him. The repeater is about 2000 feet above him (not including the tower height). He is in a valley that has little altitude variation until his signal reaches the mountain.

This info is available from Google Earth using his numbers.

All of this leads me to think that something else is wrong. I can hit a repeater 20 miles from me with 5 Watts and its antenna is on a 300 ft tower. My antenna (half wave end-fed dipole) is on a 20 ft mast.

I have tons of deciduous trees between me and the repeater but the signal is always solid with no noise on it (I don't have an S-meter) and I have never had a report of noise on my signal until I tried to carry on a conversation with 200 mw output power.

Cheers,
John

I'd just put up the yagi, and likely be done
with it. That should get you over the hump well
enough to use the repeater.
You probably don't even need a rotor.
Just aim it at the bad machine, and if the
other one is as good as you say, it will likely
be usable even aimed at the other one.
Or you could use a switch to go back to the
vertical. If the coax run is long, don't use
thin coax like RG-58 or it's ilk. I consider
RG-8/213 types the minimum for anything semi
critical. And you can get better than that.
Doesn't pay to use a gain antenna if you lose
a large chunk of it in feed line losses.

Hello John,

With Google maps, results (distance and bearing) are similar (based on
the data given by Kirk).

If the trees south of his antenna are the problem (I am not
convinced), he needs to cut lots of them. They are about 150m from
his antenna, and at that distance first Fresnel zone width is about
30m (100ft).

It seems flat when looking to the activities in the valley. I hope
somebody can make a path profile and loss simulation to see what is
the real obstacle.

With kind regards,

Wim

I was up on my neighbors property along the path to the repeater and the
quantity of trees is a lot more than I had remembered. Since this is
tree growing/logging country it is not feasible for me to be cutting
huge amounts of trees. The deciduous can go but there are to many
conifers on both properties to cut just for signal. You are correct on
the distance to the grove and it is the, I believe, the only impediment.

There may well be something wrong with the antenna. I don't have an SWR meter handy but will try and borrow one from a club member. The J-pole was beat around quite a bit over the years but since the radio has a limiting circuit if the SWR is too far out of whack I am assuming it is fairly close. It will transmit of full power. I'm using 75' of professionally assembled RG8X which is required to get from the radio to the antenna.

Not to make light, one of these poplars is tons in itself. They are easily 70' tall and 24" diameter. I truly appreciate all the help from everyone.

That's quite a drive. Thanks for the numbers. I've ignored the
antenna heights as they don't seem to make much difference. 31 km (19
mile) path length. The K7JEP repeater seems to be on a wide flat part
of a hilltop. Pointing downward, it may not clear the edge of the
flat part if the antenna isn't high enough. Difficult to tell without
photos or numbers. Not much you can do at your end to fix that. Any
chance you have a photo of the K7JEP repeater antenna location?

Otherwise, the path is line-o-sight, and should be quite usable with
your American Legion J-Pole. Of course, a yagi would be better, but I
think tinkering with your J-pole, coax, connectors, and radio may be a
better solution (assuming the repeater is working properly).

Radio-Mobile will give you the expected coverage area and signal
strengths from your location. However, it's a tricky program to
master and will require some patience and practice. There are
tutorials. For example:
<http://www.pizon.org/radio-mobile-tutorial/index.html>
<http://www.bcwireless.net/moin.cgi/RadioMobile/Tutorial>
<http://radiomobile.pe1mew.nl/>
etc.
Also check YouTube for various video tutorials.

The American Legion J-pole is rather critical, especially the dual
band flavor. The vertical section of electrical wire between the coax
connector and the part where it's wound around the driven element is
the tuning adjustment. Move it slightly and it's mistuned. You'll
need a VSWR meter to re-tune it.

>I'm using 75' of
>professionally assembled RG8X which is required to get from the radio to

RX-8x is 4.5dB loss per 100ft. Half your power is being lost in the
coax.

I have heard from a club member that the repeater is weak and it has
been overrun by one on the coast! He is much farther away than me and
in a much less desirable location, signal wise.

I have been out of HAM radio for about 15 years so am having to relearn
quite a lot. Had a brain injury, doh!, so lot's of what I knew went bye
bye. Lot's of holes in the memory. I will find out about the repeater
during the next club meeting. Specs and all.

I wonder whether he might have his antenna sitting in a particularly
deep multipath cancellation null.

I help run a repeater located about 4 miles from my house, which is up
at about 80' AGL on a hospital roof. There's an office building
blocking direct line-of-sight path from my house to the repeater.

For a few weeks, several years ago, I found myself unable to
successfully open up the repeater using my base station, even while
transmitting 50 watts of power from a good-quality commercial 2-meter
antenna located a few feet above my roofline. Had no trouble with any
other repeater in the area, or with simplex operations. The
feedline/antenna system measured out just fine... no reflected power
worth speaking about.

I moved the antenna mast about 2' to one side, and was then able to
open up the repeater full-quieting with 100 milliwatts.

All I can figure is that there must have been a *very* deep multipath
cancellation effect playing out... maybe interference between a
edge-diffraction path involving the office building, and reflections
from nearby trees. Moving the antenna a fraction of a wavelength
changed the path lengths enough to eliminate the cancellation (or
reduce it by a large factor).

One of the things to know about the American Legion J-pole (and most vaguely-similar J-poles) is that it has no feedline or mount-point isolation to speak of. The outside of the feedline coax, and any pipe or tower or other metal to which you strap the antenna, become part of the antenna's ground system, and can radiate a significant amount of RF. This can interact with the RF coming from the main radiator, and significantly alter the antenna's pattern... it no longer behaves like an idealized half-wave vertical radiator.

In most installations this doesn't seem to matter all that much... but it's possible that you've got some sort of weird interaction (feedline emissions, reflections from the ground or nearby metal, etc.) which is creating a null in the antenna's pattern in just the wrong direction. If this is an issue (not all that likely but perhaps possible) you could insulate the antenna from the mounting mask, and install a choke (e.g. a few ferrite cores) on the feedline just below the antenna.

Also, the American Legion J-poles are subject to a couple of forms of mechanical/electrical failure after a few years. The plastic insulator which spaces apart the radiator and matching arm can degrade (UV from sunlight is the main offendor, I believe) and crack, allowing the two arms to change spacing. More subtly, the connection between the two arms and the metal base can degrade... it's aluminum-to-aluminum using a set-screw, and the connection can loosen and corrode.

It might be worth checking the spacer (replace if necessary), and checking and tuning up the set-screw connections (squirt with Liquid Wrench if necessary, loosen and remove, take out the rods, clean the ends of the rods and the mounting holes in the place, dab with NoAlOx or a similar corrosion-blocker, reassemble and tighten).

> I'm using 75' of
>professionally assembled RG8X which is required to get from the radio to

>the antenna.

That's probably costing you about half of your power (assuming a
typical RG8X-type coax). Some lower-loss types (e.g. LMR-240 are
better than this.

From: petem001@gmail.com
Message-ID: <irhbl5cqv1@dont-email.me>
Source record: 4701

Anyone know where I can find a dual band 2 meter 70 cm beam ?

Trying to build a beam for both band and I want to put it on 90 degre rotor
to make it work in horizontal and vertical so I would need only one coax
line for 2 m v/h and 70 cm v/h

thanks..

Ok. Might be a sick repeater. That would explain quite a bit.

>I have been out of HAM radio for about 15 years so am having to relearn
>quite a lot. Had a brain injury, doh!, so lot's of what I knew went bye
>bye. Lot's of holes in the memory.

I have a slight idea of what's that's like. I had a triple bypass
operation in 2002. They're not sure what happened but the result is
that my memory around that time is like Swiss cheese. It's a mix of
things that happened that I don't remember, and things I remember that
never happened. Fortunately, things got better after about a year for
me. Hopefully, you'll do as well. Also, my neighbor had a brain
tumor removed. She's fine, but has the same scrambled memory problem.

I gave up ham radio from about 1975 to 1992. I was working designing
radios and working in commercial 2way. The last thing I needed was
ham radio after hours. Welcome back.

>I will find out about the repeater
>during the next club meeting. Specs and all.

Good idea. I assumed that you had already done that. If the specs on
the repeater (tx power, feed line losses, antenna gain, antenna
height, lat-long) were known on the repeater, I can calculate the
signal strength you should expect at your end.

Anyone any experience of nesting hentennas for multi band use? I'm thinking of a 6m hentenna inside a 10m one.

My first thoughts are that it should work, like nested cubical quads.

That is always a possibility, Dave. I have seen similar situations and I
am not surprised at your findings. It is one reason I suggested moving
his antenna, even slightly.

His latest post may also indicate that there is a repeater problem. So,
I hope he posts his findings after his meeting with his club.

Cheers,
John

The results are all over the map. A piece of Cable TV cable might not be a bad choice, if you can scrounge one. The 75 ohms probably isn't a big deal.

At 144 MHz, bigger in diameter almost always beats fancier dielectric (that is, the .405 inch RG-8, RG-213 flavors will usually beat any of the quarter inch cables (RG-6, RG-8X, LMR240, etc.) because dielectric losses aren't a big driver.. it's the IR loss in the center conductor. RG-11, for instance, has less than 1.2dB loss for a matched 75 foot line, and for the 1.5:1 mismatch, the loss only goes up 0.1 dB. (RG-11 type coax has a solid dielectric, and is pretty darn rugged stuff)

75 feet, at 144 MHz
LMR240 - 2.2 dB
Belden 8215 (RG-6A) - 2.5 dB
Belden 9258 (RG-8x) - 3.0 dB
Tandy RG-8x - 3.1 dB
Belden 8267 (RG-213) - 1.9 dB
Wireman CQ110 (RG-213) - 1.6 dB
Belden 8237 (RG-8) - 1.7 dB
belden 8213 (RG-11) = 1.2dB

Elk makes a 2m/70cm dualband log-periodic beam.

http://www.elkantennas.com/

I keep one in my ARES/RACES go-kit setup... portable, easy to set up
and tear down, very useful for field deployments out in fringe-
reception areas.

Huh? 75 ft of RG-11 has almost 8dB of loss at 146MHz. 75 ft of LMR240
has 9.7dB of loss at 146 MHz.

I won't go through your entire list.

John you need to see where you went wrong. The numbers Jim listed are either correct or very close. I did not bother to do the calculations, but looking at a 100 foot chart, the numbers are very close and no where near the numbers you have.

I thought you may have looked at the web page and missed it defauls to meters, but that does not seem to be the case to me.

You are correct, Ralph, and I apologize to the group for my error. I did
indeed put meters rather than feet into the calculator.

Again, my apologies, and thanks, Ralph, for correcting me.

Cheers,
John

1260. FS Heath HM-2102 VHF SWR meter

It is mounted on an angle bracket about 12" from a mast 20' above my
metal roof. The mast is isolated from roof but is not yet grounded.

My spacer basically disintegrated. I replaced it with 1/2" pvc pipe. I
measured the spacing at the base and got it as close as possible.

I will check out the other connections. There is obvious aluminum oxide
on the assembly so it is very possible it is down between the parts.

I'll get up on my steep metal roof after the rains stop. :-)

That's what I used..
Sure you got feet and not meters?

B9219, 75ft, 146 MHz = 1.811dB

Yes, Jim, Ralph pointed that out to me yesterday and I posted an apology to him. I see that I should also analogize to you for my mistake.

Thanks to you both.

John

I have a Heath HM-2102 VHF SWR meter 50-160 MHz
0-25 and 0-250 watts. Excellent condition.

I'm *asking* $40 plus shipping.

It can be viewed at:

http://home.comcast.net/~hsknoll/site/?/photos/&PHPSESSID=29ec62ea0bf1fe4d25e318b011cf0bbf

or

http://tinyurl.com/yktwxpz click on photo to enlarge it.

Darn newsreader that didn't have all the messages loaded.. I saw Ralph's comment and your reply. Such is life..

Now, if you want some high loss coax.. can I interest you in some tiny coax made of stainless steel? It's for cryogenic applications so it has very, very low thermal conductivity, but it also has really high loss. I don't think you want to be running kilowatts (or even watts) through it.

Well, thanks, Jim, for your kind offer. However I have plenty of lossy cable now. I only use in the lab because other options are difficult to handle.

Cheers,
John

According to the loss calculator at Times Microwave the loss at 144 MHz
for a 75 length of LMR 240 is 2.952. 100 METERS is 9.687.

Perhaps you misread.

Not a Sea Story and relevant to my learning an important multipath lesson:

In 1974, I was on an aircraft carrier at a pier in Long Beach Shipyard. Ship's TV sigs not so good, so I ran a cable from the CPO lounge TV out and up to a flight deck catwalk. On the catwalk, I mounted a small all-channel antenna on a mast strapped to the rail. The transmitters (Mt. Wilson) were located away from that side. All very good pictures. In about two months, when the ship moved into drydock, it was turned 180, so I rotated our TV antenna to compensate. No good. Signals arriving across the flight deck were all awful. Unwatchable.

I suspected reflections from the flight deck, so I moved the antenna all the way aft, where it was receiving through clear air again. Bingo! Even through the added 150' of cable I needed, we got our nice pictures back.

Im convinced that my J antenna that I used while camping radiated
mostly verticaly. The situation sounds very similar to yours. I
couldnt hit the repeater back home with 50 watts using the J- while
my wife could make contacts on her HT on the same repeater, Her
antenna was either a telescoping .5 wl or 5/8 wl connected directly to
her HT.

Hello Kirk,

I sent you a PM with a result from Radio Mobile.

It took a long time to get RMW working, and getting the terrain data into the SW.

It is 10 years ago that I used RMW and that computer I don’t have anymore. I had to start from scratch. First checked with Dutch terrain data to see whether the results are meaningful.

When you look to the path profile, you have a huge margin (received power -76 dBm). I used 10W into a 2 dBi antenna (on both sides). I attached the path profile as generated by RMW (Personal Mail only).

Even reducing your antenna height to 1m AGL gives sufficient margin (Prx -86 dBm). I used 30m AGL for the repeater antenna. You have 1 degree elevation towards the repeater, that is huge (we don't have that in the Netherlands).

Assuming the data is correct, it is really strange that you can't hit the repeater. I couldn’t find were to set vegetation and cities, but even this shouldn't be a problem. I hope some other people can confirm the results from RMW.

With kind regards,

Wim

Hey, Kirk -

After reading Wim's response, I am more convinced than ever that you
have a problem with your antenna, coax, or transceiver.

What type of coax are you using? Could it have gotten water inside? Are
you using the coax that you used 10 years ago?

Try to think of other question similar to these and we'll get to the
bottom of this.

Cheers,
John

Radiation resistance can be, and is, defined differently by different writers. Often the term is used without clarifying definition, and of course that leads to trouble. Beware any time an author throws around "radiation resistance" without carefully defining how he means it. There's a nice section (section 17; page 118) on it in King's "Antennas" chapter of King, Mimno and Wing's "Transmission Lines, Antennas and Wave Guides." I highly recommend reading that passage, though I know that not everyone likes King's writing as much as I do. (I may be able to supply a PDF of it, if you can't find the book.) Generally, radiation resistance is associated with power actually radiated by the antenna: i^2 * R(radiation). One possible definition is "that portion of the resistive component of the feedpoint terminal impedance that represents radiation." But when the feedpoint is not at a current maximum, "radiation resistance" is sometimes (often?) taken instead to be the resistance which, when multiplied by the square of the current at the current maximum, would result in the value of the radiated power.

Presumably the "terminal resistance" is the resistive component of the impedance seen at the antenna's feedpoint terminals. It's generally a good idea to specify that the current is the same magnitude and opposite direction in the two feedpoint terminals, and that they are closely spaced--a tiny fraction of a wavelength apart.

The difference between the two represents power dissipated in the antenna itself. Of course that's generally a pretty low percentage of the total in self-resonant antennas, but in short antennas (loaded dipoles and monopoles, and tuned loops that are very small compared with the wavelength) the power lost in heating the antenna and associated loading reactances can be significant.

Cheers,
Tom

Orfanidis has an explanation in Chapter 15 of his online
electromagnetics textbook
http://www.ece.rutgers.edu/~orfanidi/ewa/ch15.pdf
page 612

Not a very complete discussion, as might be found in Kraus, but at least
it's online.

There's also Prof. David Jeffreries's website
http://personal.ee.surrey.ac.uk/Personal/D.Jefferies/radimp.html
"The classical way to calculate the radiation resistance is to surround
the antenna with a hypothetical closed surface in the far field,
calculate the values of electric field and Poynting vector on this
surface in terms of the antenna terminal current I, integrate the power
flow per unit area, represented by the Poynting vector, all over this
surface, to determine the total outward travelling power in watts, and
equate this power to the quantity II*Rrad/2 as discussed above. "

Thanks, Tom. That pretty much answers my question.

Thanks also to Jim.

John,

I believe it is either the trees or the antenna. The coax is new and
the transceiver worked fine last time I used it. Also works fine with
this setup getting into the repeater on Schweitzer , 145.230, with 5
watts and the signal report from a gentleman I spoke to was 59. That is
a clear shot and a few miles closer. Although the profiles show there

should be a clear shot to the .780 repeater I can gurantee there is a wall of trees on the first little ridge on the profile. I found that my club, which I've only been with for a month, has an SWR meter and an antenna analyzer. I hope to borrow them to see what's up. In the meantime I will pull the J-pole down and clean it up as suggested. There is considerable aluminum oxide on the outside of the parts so there may be some between the base and uprights. When I put it back up I will move it 180 degrees from it current location. That will only move it about 2' but who knows.

Are you pointing to the trees that are about 160m south of you and
below (that are also visible in google earth)?

If so, I can't believe that this will put down your signal from about
-76 dBm towards unreadable (so in the -117 dBm range). Reason: the
first Fresnel zone has a diameter of 36m (118ft) at 160m (525ft) from
your antenna and I don't expect all trees are over (for example) 20m
(60ft) height.

I may have missed it, but have you tried riding around with a mobile rig and
seeing if you can hit the repeater ?

A SWR meter may not tell you much about the antenna. I think you are using
rg-8x. The coax will have enough loss at 2 meters to give a very low false
reading. YOu can probably unhook the coax from the antenna and only show
about a 3:1 swr.

Of course. It all makes sense now. Feeding a 1/2W dipole in the center causes one to measure approximately the Rr. However the dipole can be fed at some other point. Even fed at one end where the feed point resistance can be in the hundreds to thousands of ohms.

So, radiation resistance is a convenient device (along with current at that point) that we use to represent power "lost" from the antenna through radiation. Good. I can understand that.

Gotta be very careful of the definitions. It was in Kraus' Antennas For All Applications that raised my question.

That, too, is understandable.

> Cheers,
> Tom

Thanks again, Tom, for this.

Also, I understand Jim's reference to integrating the volume to get the radiated power and, hence, Rr. Thanks, Jim.

Cheers & 73,
John

The antenna itself could not have radiated a significant percentage
vertically if used near the design frequency. It is effectively a half
wave vertical if properly constructed and fed. Fed being the most critical.

If you didn't choke the coax properly and it was parallel to the ground
you may have radiated some towards the zenith. But I doubt it was most.

Blah de blah

How many amateur radio operators use this kind of academic preening
when they are putting up a dipole.

Too much hand-waving here to be useful to most folks.

The Cushcraft A3S beam has 3 elements. The driven element is setup to
be used as a rotatable dipole on 40 meters. It works a lot better than
it sounds.

The spacing of the elements on the boom does not change.

Thanks.

Between the Rotor and the A3s/ and the Dipole getting it up to 40ft should be a real pain.

Hello Kirk,

Did you receive my PM with the path profile and propagation
prediction from RMW?

I now added clutter because of trees (I used 30m high trees with 80%
density). The predicted signal strength goes down from -76 dBm to -81
dBm (10W transmitters into 2 dBi antennes, your height 10m, repeater
heigth 30m).

Jeff (AE6KS) sent me a .kml file with the path profile from you to the
repeater on the hill, there is good agreement between the data I used
in RMW.

So before going to the paper/plywood production plant, you may search
for some other problem.

With kind regards,

Wim

Hello,

After 10 years I started again with Radio Mobile mapping and
propagation prediction program. One can export path profile data via
the "Radio Link" calculation pane. The result is a text file that you
can modify (to change the path profile).

Is there any possibility to import a modified path profile again, so
that a new propagation prediction simulation can be done

With kind regards,

Wim

It is about the same size & weight as other multiband beams. The 40 M
add on seems pretty expensive but I do use it a lot.

Also, Mine is mounteds on a tilt-over, crank up from the late 1970's.
Two electric winches, no sweat for an old man.

Also, there is a Homebrew tilt mechanism...

You can check it out at
http://dixienc.us/TiltOverGadget/TiltOverGadget.htm

I have also found it useful on WARC bands simply by using a tuner.

1292. Re: The Lazy H does not seem to exhibit any gain over a dipole in the real world

Newsgroup: rec.radio.amateur.antenna
Date: 2011-05-30 18:13:56 UTC
From: Michael <google@shadowstorm.com>

Source record: 4743

Well I've worked with the center fed Lazy H antenna design on 10 meters for several few weeks now. I tried 1/2 wave spacing between the top and bottom elements, 5/8th wave spacing between the top and bottom elements, I put it up at 40 feet and 50 feet at the top wire, I tried different lengths of 450 ohm feed-line, and this antenna consistently under performs a 1/2 wave dipole cut for the same frequency. A simple 1/2 wave dipole consistently out performs the center fed version of Lazy H antenna even when the Lazy H is given a 20 foot height advantage over the lowly dipole. I even put up the Lazy H in two completely different locations over 180 miles apart. I also tried two completely different antenna tuners (Dentron MT-3000a and Drake MN-75 with the 4:1 balun installed). Out of over 200 A/B test the Lazy H antenna only out performed the dipole on one test with a station in Texas just before the propagation faded out for the day, The next day when the propagation was back I heard the same station on the same frequency and the dipole out performed the Lazy H for the rest of the day. I'm not sure what special propagation mode is required for the Lazy H to have some gain through some pin hole direction, but the version of the Lazy H center fed with 450 ohm ladder line back to the antenna tuner is a complete failure. I even re-built the antenna from scratch using a different piece 450 ladder line for the inter connecting piece. I also verified the length of each 1/2 wave section with a tape measure. I verified with an ohm meter that the top left element was connected to the bottom left element and the right top element was connected to the bottom right element. I verified there was no unexpected connectivity between the left and right elements, and I verified both sides of the ladder line were connected back to the antenna tuner. I made sure there was no twist in the ladder line connecting the top and bottom elements.
I would like to petition the ARRL to remove the center fed Lazy H from the antenna handbook as it clearly does not work as specified. A lowly mono band dipole on the same design frequency will consistently out perform the center feed Lazy H even when the Lazy H is given a 20 foot height advantage on10 meters.
Before any of you reply with charts and graphs from EZNEC software, turn off your computer, go out in the back yard, and actually build a center fed Lazy H antenna with 450 ladder line all the way back to the antenna tuner. Then do real world A/B comparisons with a plain old mono band dipole cut for the same frequency, and you will find I am telling the truth. The center fed Lazy H does not have any gain over a 1/2 wave dipole broadside to the antenna. None.

Here is what you will fine if you actually build the center fed Lazy H and compare it to a 1/2 wave mono band dipole cut for the same same frequency;

1) Your tuner will have to use extreme setting to match the Lazy H.
2) In some instances the tuner will not be able to match the Lazy H depending on the length of the ladder line feeding the antenna. You may have to increase or decrease the length of the ladder line feeding the Lazy H to get your antenna tuner to match it.
3) A 1/2 wave dipole will beat the Lazy H 99.99 percent of the time in it's favored direction even if the Lazy H is given a 20 foot height advantage over the dipole.
4) An extended double zepp with a 450 ohm matching section back to a 1:1 balun and then to 50 ohm coax cut for the same frequency and hung from the same ropes previously used to support the Lazy H will blow the Lazy H in the dirt.

In a nutshell, this antenna sucks!

Hi Michael,

I'm sorry to hear you think the lazy-H sucks. I used one on 20m years ago and it worked just fine--and no trouble in matching it with a tuner.

However, I have a suggestion: Let's say you space the upper and lower radiating elements by 180°, which is 1/2wl. If you now use 450-ohm window line, the velocity factor for the line attaching the two elements together makes the electrical length of the line greater than 1/2wl, which means the phasing between the upper and lower elements is

no longer correct, and therefore will not provide the expected gain. I'm not sure how much phasing error that will produce, but it's an issue you should consider. Correctly constructed, the lazy-H will definitely out perform a 1/2wl dipole, so if it doesn't for you there is sum ting definitely wong!

If you feed at the center of the line connecting the two radiating elements the phasing will be correct regardless of the velocity factor, because the length from the center feed point on the connecting line will be the same from that point to each radiating element. With this configuration of feeding don't put a twist in the connecting line--the two radiating elements MUST be fed IN PHASE! If they're fed out of phase the array will look like an Adcock direction-finding antenna, with a deep null in the radiation pattern in the broadside direction.

Just my thoughts,

Walt, W2DU

Not many, certainly... but I would offer that those who do are able to enjoy the hobby more thoroughly than those who don't. Whether or not that additional enjoyment makes up for the extra time needed for learning, well, that's up to each individuals.

I personally care about these things, and even for hams who think they don't... most all of them have probably thoughts to themselves, at one point or another, "Hey, what happens if you feed a dipole off-center?," and it's nice that someone else has already gone through the effort to figure it out such that the answers are readily Google-able! :-)

1296. Re: The Lazy H does not seem to exhibit any gain over a dipole in the real world

Newsgroup: rec.radio.amateur.antenna

Thanks for your input Walt, but I already thought of those things.
I definitely made the antenna correctly. According to the ARRL
handbook when center feeding the Lazy H increasing the spacing beyond
1/2 wave makes the gain go up until the spacing reaches 5/8ths wave.
The handbooks states 5.9 dbd gain for 1/2 wave spacing and 6.7 dbd for
5/8ths wave spacing. In the real world this antenna does not have any
gain over a 1/2 wave dipole when center fed with 450 ohm ladder line
all the way back to the tuner. The phasing was correct. On 14 MHz
where it becomes two stacked dipoles the SWR comes down and the
performance goes up, but on 28 MHz it consistently lags behind a
dipole. I rebuilt this antenna twice. If you actually go to the
trouble of making one for 10 meters, and compare it to a real world 28
Mhz 1/2 wave dipole, the Lazy H will fall far short of the predicted
gain.
I have been a ham since 1986. I wondered why I had heard so few
hams using a Lazy H, and the one time I recalled hearing one the
signal was weaker than the other hams using a dipole. I assumed at
the time that I must have been off the side of the other ham's Lazy H,
but after my real world test who knows.
I'm going to remove the center feed from the antenna this week, and
rework the Lazy H for end feed with a twist, a matching stub, and 1/2
wave spacing. Hopefully the end fed version of the Lazy H will live
up to it's text book gain. I'd really like to have that 6 dbd gain
along with the nulls off the sides,

One other thought, Michael, is that if you made the lazy-H with 1/2wl spacing for 20m and then use it on 10m, the spacing is now 1wl. I haven't seen any figures for that spacing, but isn't it possible that with that spacing the gain might not be what you expect? Especially if it works properly on 20m?

Hi Walt,
I initially made the Lazy H for 5/8th wave spacing on 10 meters.
When that did not work I reduced the spacing to 1/2 wave spacing on 10
meters. The 4 half wave elements are 1/2 waves on 10 meters. The
antenna design is really pretty simple. I did make some contacts with
this antenna and I received some good reports, but the dipole
consistently out performed the Lazy H, There was one contact in
Bermuda that said the Lazy H put in a stronger signal from South
Carolina, but there was alot of fading at the time. Even when the
Bermuda contact said the Lazy H put in the stronger signal the dipole
was receiving the stronger signal from Bermuda.

I looked at that antenna in a handbook years ago. Could not tell from that how it is mounted. Do you mount the elements one over the top of the other, or do you mount them sideways like a 2 element horizontal beam ?

Yes. It is mounted horizontally.

I sort of think also, the Lazy H (think colinear?) should be fed and phased with 75 ohm line.

On Mon, 30 May 2011 14:48:45 -0700, walt wrote:

If you feed at the center of the line connecting the two radiating elements the phasing will be correct regardless of the velocity factor, because the length from the center feed point on the connecting line will be the same from that point to each radiating element. With this configuration of feeding don't put a twist in the connecting line--the two radiating elements MUST be fed IN PHASE! If they're fed out of phase the array will look like an Adcock direction-finding antenna, with a deep null in the radiation pattern in the broadside direction.

Just my thoughts,

Walt, W2DU

People who are running NEC models, particularly NEC2 as opposed to NEC4, tend to be interested in this kind of thing.

While building antennas and running them up the flagpole/tower/tree to test is fun and enjoyable, you can save a whole bunch of time with some modeling ahead of time (and besides, sometimes the weather isn't good for antenna building/testing)

And there's a whole raft of "off center fed" dipoles of one sort or another out there, particularly for multiband applications, so it's nice to understand that what's really going on is that the feedpoint impedance you see is basically the same as feeding at the center, but run through a "transformer".

A bit of theory helps one evaluate all the "secret recipe worked 1000 countries on top band with 1 Watt and a 3 foot long antenna" stories too.

Another point to consider, Mark, is that the azimuth beam width is
narrower with the lazy-H than that of the dipole. So perhaps the
apparent lower signal level is in directions off the side of the
radiation pattern, where one would expect the signal level to be lower
than that of the dipole at the same angle.

Me, me, me. Even the simplest antenna is influenced by nearby
structures, towers, poles, elevation, guy wires, position of coax
feed, chain link fences, and grounding system. That makes a simple
dipole not very simple. I've helped a few local hams model their
houses allowing prediction of takeoff angles, mysterious nulls,
optimum height, and cut length. While modeling (I use 4NEC2) does
take some learning and understanding, it does offer an improvment over
the tradition ham radio cut-n-try.

Or another way to think about it (perhaps closer to what's going on)
is that it's like changing the position of a tap on a resonant tank
circuit. If you get into building RF filters using coupled
resonators, you'll appreciate that changing the tap position on the
input and output resonators changes the filter's operating impedance,
as seen at the input and output, though just as in the off-center fed
antenna, the current distribution in the resonator (or antenna)
changes relatively little. For the case of the antenna, of course,
you have to decouple the transmission line very carefully if you feed
it off-center -- or else just allow for the fact that there _will_ be
antenna currents on the transmission line e.g. an end-fed half-wave).

I agree, Jeff.

I like antennas that are naturally short-circuited by design and can be grounded, making the feed point essentially grounded for DC and lower frequencies. One such antenna is the folded unipole. Its only problem is that the feedpoint resistance is about 120 or so ohms.

So, I had this idea. The usual monopole (or ground plane) has about 30-35 ohms resistance. To get 50 ohms it is common practice to droop the radials about 45 degrees. Since that raises the feedpoint resistance, would raising the radials lower the feedpoint resistance of the folded unipole and, if so, what effect would it have on the pattern?

EZNEC said to raise the radials of the folded unipole about 23 or so degrees to get 50 ohms and the pattern would not be affected.

So I built one and it works swimmingly. I had to make some minor adjustments in element lengths but that was fairly easy with the vector voltmeter. Hooray for modeling.

Cheers,
John - KD5YI

Slick... and I bet that the appearance of it raises the occasional
question and/or eyebrow!

The matching approach I've usually seen for folded monopoles, is to
use a quarter-wave transformer made out of (e.g.) RG-6 or another
75-ohm coax... this brings the impedance down to something not too far
from 50 ohms. Your method avoids the need for this.

If I were to build one I think I'd stick a fat cap over the end of
each raised radial... just to reassure myself that I wasn't setting up
an "automated pigeon-skewering device" of sorts :-)

Hooray also for using your head, John, and realizing that raising the radials would _probably_ have that effect -- then having that verified by a model, and then by an antenna that works well for you in practice.

Another way that should work: make the two parallel conductors different diameters, with the correct spacing. You might also try making a self-supporting grounded quarter wave, resonant with its radials, and fed with a parallel conductor that doesn't go all the way to the top of the quarter wave...

So there are three different arrangements, perhaps with pretty similar electrical characteristics, and you can then pick among them for the one that suits your construction practices the best. Perhaps there are some more "grounded" monopole designs you throw into the mix.

Yes, if you're "just throwing up a dipole," maybe you don't worry about things like this, but there are those of us who like to think a bit deeper about things. I can only hope I remain infinitely tolerant of those who like to think much deeper than I about many things.

Cheers,
Tom

As a matter of fact, I can see where just jumping into it without the benefit of modeling would probably have resulted in giving up on it. I had to adjust many things (such as radial tilt) before I learned about how things were going to be affected. Modeling is like having an antenna breadboard but a whole lot less work.

C'mon, Tom. You're a very knowledgeable person and I value your input. That's plenty deep.

By the way, I used Walt's inherent balun to make a diamond-shaped antenna which needs no additional balun. It is 50 ohms at the feedpoint. It, too is inherently short-circuited and, with the inherent balun, probably groundable.

It was an interesting exercise that went like this:

1. I like a loop for the inherent short-circuit.
2. It has about 100-120 ohms terminal resistance. I want 50 ohms.
3. It needs a balun. But, I don't really want one.

A folded dipole is about 300 ohms. A half-wave shorted transmission line is about 0 ohms. So, if you take a shorted half-wave transmission line and spread the wires apart at the 1/4W point all the way to where it becomes a folded dipole, it seems to me that the terminal resistance will go from zero to 300 ohms and 50 ohms is in there somewhere.

I tried it in EZNEC and found that to be the case. I found that, if the acute angle of the rhombus is about 51.5 degrees, then the terminal resistance is about 50 ohms (adjust perimeter along with angle to get 50+j0).

Ok, fine. That takes care of everything but the balun. In Walt's Reflections III, he discusses the half-turn bifilar loop (page 22-10). But what was intriguing was the inherent balun. Aha!

So, after modeling as well as I knew how, I constructed a rhombus (diamond-shaped) antenna with the right half of the diamond being coax (inherent balun) and the left half of the diamond being 14 ga wire.

The velocity factor of the coax means that its electrical length is about .6 of a half wave (or .3 lambda) where I wanted 1/4W, but it is close enough. I have not been able to measure current on the outside of the coax, but it may be because I have not yet created a sufficiently sensitive probing method.

I've not yet installed it. Maybe in the next few months I can get to it.

Cheers,
John - KD5YI

As an aside, I found it time consuming to adjust angles and repeat the source impedance test in EZNEC. So, I created an Excel spreadsheet where I could simply input the perimeter, the acute angle, height above ground, wire gauges, and number of segments and wrote a short VBA to gather the spreadsheet results and create an EZNEC importable file.

Man, what a time saver.

73,
John

Are you feeding this with coax? Why not use a big choke at the
feedpoint on the outside of the coax (i.e. a bunch of suitable ferrite
toroids)?

It's not like antenna itself cares which side is connected to shield or
center conductor (as long as no current is being carried on the outside
of the shield?)

It should work basically identically as a scheme with a coax balun, so
you could choose which ever is mechanically or cost-wise more
convenient. (I happen to have a box full of 31 mix toroids for such
things, you might happen to have extra coax or a clever way to support it..)

I don't understand. The built-in inherent balun needs no choke.

But doesn't it need an extra length of coax on one of the sides?

No. The left-hand side is #14 wire while the right-hand side is coax (obviously left and right can be reversed). A BNC female is at the bottom, bayonets downward, terminals upward.

```
o
/ \
/ \
/ \
/ \
+ +
\ /
\ /
\ /
\ /
oo
```

The coax (right side) is connected as usual to the BNC and bent as shown. However, the coax's center conductor *only* is connected at the top to the #14 wire on the left of the diamond. The bottom end of the #14 wire is connected to the BNC connector shell at the bottom.

The piece of coax on the right forms the balun. It is close to 1/4W internally considering the velocity factor of the coax, but about 1/2W externally.

As I said, it isn't exact. It measures very well here. I measured VSWR of 1.02 but that was not the important part of all this. I have yet to measure current on the transmission line from the BNC to the source to my satisfaction.

If I can supply clarifying info, let me know.

73,
John

I meant to give Walt (W2DU and Reflections III) credit for the inherent balun as before. My only contribution is my discovery (or re-discovery) that the terminal impedance of the antenna can be adjusted within the limits mentioned in my earlier post.

One other post script: As the quad departs from a square, it seems that the antenna gets a bit more touchy with regards to dimensions. It is difficult to tell for sure, though, since I'm doing this at 434 MHz and *everything* is touchy there.

Cheers,
John

I "MAY" have figured out what was wrong with the Lazy H. This is a
tentative post.

The Lazy H is located in Charleston, South Carolina and it is
broadside to Southern California. It should be aiming just barley
north of West and just barely south of East. The first clue came when
a station in the Caribbean gave me a 20 over S9 report. That
direction should be in a null spot. The propagation has been coming
in from Texas, Southern California, Central and South America, and the
Northeast (New York, Mass, New Jersey, etc). Well today the
propagation rolled in from the North west, and I saw a signal increase

from a station in Iowa when I compared the Lazy H to the dipole. That is not the direction the Lazy H is facing, so it occurred to me there might be something skewing the propagation angle of the antenna to the north west and south east. Since there has not been any propagation from the North/west direction until today I had nothing to test it against. I went outside and noticed the 450 ohm feed line was not coming away from the Lazy H at a 90 degree angle. It was more of a 45 degree angle. I added some length to the 450 ohm ladder line, and then repositioned the feed line to come away from the Lazy H at a 90 degree angle. When I went back to test the antenna it was beginning to show gain in the intended direction. Also the tuner had an easier time matching the antenna. I may have to play with it some more, but I may have found the missing 5.9 dbd gain with 1/2 wave spacing. I'm going to keep my fingers crossed and hope I don't have to retract this post.

That sounds like something that would be valuable to others, too,
John. You might think about making it available...

BTW, I do think pretty deeply about a lot of things, but there are far
more I don't bother with. Still, people who do think deeply about all
those other things hold my respect for what they do, whether it's
topics I have any interest in or not. Along with that is an
understanding of how important it is that we can freely share what we
learn with others.

Cheers,
Tom

Posting-Frequency: posted monthly
URL: http://www.panix.com/~rram/usenet/rram/index.html

Changes followed by "|".

After a 30-day public discussion and feedback period to gauge reader
opinions in March of 2009:

http://groups.google.com/group/rec.radio.amateur.moderated/browse_thread/thread/d7d337db35
f23326

the rec.radio.amateur.moderated Moderation Team has decided to consider
amending its charter, and permit limited simultaneous crossposting to
rec.radio.amateur.moderated and one other unmoderated
amateur-radio-related discussion newsgroup. We are currently trying
this on a temporary basis (90 days, through early July 2009), and adopt
it permanently if successful.

Approved rec.radio.amateur.* newsgroups are those that are currently
listed in the latest version of the "List of Big Eight Newsgroups" which
is crossposted monthly to news.announce.newgroups, news.groups, and
news.lists.misc.

Approved alt.radio.amateur.* and alt.ham-radio.* newsgroups are those
that have been created consistent with the suggestions in "So You Want
to Create an Alt Newsgroup" at:

http://www.faqs.org/faqs/alt-creation-guide/

Approved regional hierarchy newsgroups are those that contain either
"radio.amateur" or "ham-radio" in their names, including
uk.radio.amateur and aus.radio.amateur.misc.

We will make every reasonable effort to keep our list of approved
newsgroups up-to-date. In case we have overlooked any, and a submission
is rejected in error as a result, the rejected submitter can E-mail us
at our administrative contact address (in the signature at the bottom of
this article, and the default Reply-To for the rejection message)
requesting that it be added, and that the article be approved. We may
still choose to reject articles crossposted to any alt.* newsgroup with
an inappropriate name, including obscene language, embedded
name-calling, or encouragement of unlawful conduct.
```

Please direct any comments, questions, or criticisms to
rec-radio-amateur-moderated-request@panix.com.

It is so narrowly focused on the rhombus that I doubt it would be useful to anybody else. But, it is available to anybody who wants it.

John

I am still working on finding where the problem is. I pulled the J-pole down and checked the resistance of the separate connections. I didn't want to pull it apart if not necessary. Everything showed 0.0 to 0.1 ohms. Seems fine to me. I then cleaned the connector as throughly as possible using emory cloth inside and dremeled the outside with a fine wire brush. There was a small amount of oxidation and it appeared much cleaner and brighter after. I also straightened the two elements but they were not really that bent. You had to look down the long axis to see any deviation. They are as straight as they are going to get but I can't believe that would make much difference.

After all this I put it back up to it's original height. There was not discernible change. I was almost unreadable at the repeater.

Next I pushed up my mast a few feet more. It is a 50' pushup that normally requires guy wires. I am not using any so I am leaving considerable overlap of the sections. I would estimate it is up around 32'. Even in high winds here I saw little deflection with just the J-pole. The 3 or 4 feet I pushed it up gave me a little bit of improvement. When I win the lottery I'll get a 100' tower put up. Guess I'm stuck with this then :-)

I still think it is the trees and have taken a picture from the roof peak towards the repeater so you can see what I am dealing with.

http://www.ncc-1701a.net/Ham Radio/ForestObstruction.jpg

It is deceiving as there are many more trees behind this line on my neighbors property. I wouldn't even think of asking him to cut any.

They are money in the bank for him.

Hi, Kirk -

It looks more formidable than I had imagined. I am sure the picture will
generate some comments.

Nobody can say you aren't making maximum effort, for sure.

When will be that club meeting?

73,
John - KD5YI

Kirk -

Do you have parts on hand such as extra coax, connectors, wire, etc?

Although you have done a thorough job of examining your installation, it behoove you to make a test separate from your present antenna installation.

For example, you could simply strip 1/4WL from the end of a coax feeder and put that end on the roof temporarily. I know, not the best match, common mode currents down the line, signal launches upward, etc. But, it is simple and might tell you something.

Maybe a quick, thrown-together ground plane?

Just a thought.

73,
John

I don't think anybody asked you:

How much power are you putting out?

How well do you hear the repeater; are there times when it fades below
squelch while you're listening to other people?

(No, I don't have a 2m PA that I'm trying to unload.)

Sal,

My TM-721A is putting out 35 watts. At least that is the spec. The repeater is always scratchy and barely readable. I've only had one time when it even showed up on the S meter. That was low clouds so I assume it was cloud bounce.

I hope I don't sound to ignorant here, too often thats the
case.
But If you have a known working Wifi AP with a high end
reputation like Cisco Airnet model 2400 for instance.
They advertize 1 watt, it's one watt no funny bones about it
or busnesses wouldn't respect their higher prices and pop for
it.
Take an EMF meter like the one on Ghost Hunters TV show,
radio shack has them, and set it ten feet LOS from the AP
[Cisco] wile downloading a big video file or something large,
and set that as your "One Watt" point, now you have a
comparason, of course notice the Antenna "Type" and location.
Heck you can use a cheap NetBook with built in WiFi and
NetStumbler software to measure the IF strenth. All you have
to be sure of is the output of your "Sample" source.
My Alfa USB WiFi unit LIES!!! they claim a half a watt, NO
WAY!!! I bet if Cisco built it they wouldn't lie about that
stuff, and of course it would cost more than 60 bucks.

If the unit has high dollar choices of hard ware use a DRAC 5
net card, our Dell servers use them, When you Telnet into them
and command a shutdown, it does not argue, it shuts down even
at the cost of head crash!!!! DRAC 5 is a robotic remote
control to the backend of whatever unit you are using it on.
It's like pulling the plug out of the wall, game over, the
unit automatically Restarts unless you send a shutdown - stay
down command. DRAC 5 cards are just as cheap as NIC cards and
install the same way. See if the WiFi transmitter had a DRAC 5
option when buying, Our high end cysco stuff comes with them.

> "Beam me up Scotty, there's no intelligent life here"

Hello Kirk,

If you have access to both ends of the cable and have access to some
VSWR measurement equipment, you may measure following things (and post
them overhere):

VSWR of cable when terminated with a dummy load
VSWR of cable when open
VSWR of cable when short-circuited
VSWR of cable with J-pole antenna

Now reduce the output power of your transceiver to avoid damage

VSWR when nothing connected to the output of the VSWR meter
VSWR when output of VSWR meter is shorted.

Make sure to check the reference (forward) reading after every change
in load, as this may change due to varying load as seen by the
transceiver. You may also do these measurements with the antenna
analyser (preferably both antenna analyser and VSWR meter).

Regarding the trees, it looks dense. Sadly to mention, if it are the
trees, you have to live with this as tree attenuation at 2m is
relatively low and first fresnel zone is relatively large at > 160m.
You need to remove lots of them to get remarkable improvement and you
mentioned that you couldn't remove lots of them because of financial
reasons.

With kind regards,

Wim

SNIP2SAVE-------
It's about 600 bucks but a Cysco 2400 WiFi with PoE support
would do this, however , remoting into a router everytime you
want to scour the bands or make an AP change is a bit of a
nucense. Thats what turns people to USB Dish and Dongle
setups. You can switch AP access on the fly, with the router
you have to "Go To Work" sort of speek. It does however
benefiet your telnet skills. :-)
If I could find a lower end name "Repeater" capable AP point
unit like a NetGear or similar and program it to autologon to
unprotected WiFi access points That would Kick butt.
Thats called promiscuous mode but has moral issues.
And another turn off, Two transmitters equalls double the
Packet overhead witch converts to half the speed even if you
have a strong signal. The KISS methoud always wins for
performance in WiFi.

There are two issues that I am ignorant to;
1; is the WEB services that are built into these routers in order to program them too often is DIS-Allowed through the AIR.
Most make you connect to a "DMZ" drop [cat5] on the router to bypass the NAT firewall and administer the stats that way.
I have never succeeded in getting to that page through Wi-Fi methods. Some routers are easy to get to through the NAT drops provided on the router there are generally 2 or 3 of them. You can NULL cat5 into the things direct from a laptop, but AirNet into them? I haven't seen that [yet].

1333. Vertical on metal patio cover

Newsgroup: rec.radio.amateur.antenna
Date: 2011-06-02 17:21:31 UTC
From: Wayne <mygarbagecan@verizon.net>
Message-ID: <is8gqu$5vj$2@dont-email.me>
Source record: 4834

I'm looking into mounting a vertical (20 meters and higher freq) on a new patio cover. The cover is made out of 6 inch by 16 foot aluminum channels that interlock edge to edge across a 20 foot width. Each section is powder coated (aka...."painted"), so the sections are most likely not well connected electrically to each other.

I'm considering a 10 foot long H shaped metal structure lying on the cover, with the antenna mounted in the center of the H. Radials are a possible but not desired approach. Any other suggested methods of mounting the antenna/etc.?

Uhh.. with the test scheme you describe, there's a ton of things that could be perturbing your results: mostly because you're measuring radiated power in a single direction, which is connected to RF transmit power, but also affected (greatly) by the antenna.

Different Wi-Fi implementations may have the same RF transmitter power, but have different transmit duty cycles. Your meter is doing some sort of time averaging.

The antenna performance on your two units under test is probably radically different. The little USB pods often have a small antenna which has lower efficiency.

I doubt your inexpensive meter has uniform response in all directions and all polarizations.

You could start to compensate for a lot of the latter by making multiple measurements at different positions separated by, say, 5cm (2") moving the meter by, say, 2 or 3 feet vertically, and 2 or 3 feet horizontally.

Anyway, measuring transmit power in the far field with an meter with unknown spatial and polarization response is trickier than it seems.

In addition to that, I think the emission is frequency-hopping and may have a duty factor associated with the scheme. I think he may need a peak-power capture scheme.

Also, how is a field strength meter calibrated for emitted power with all the variables involved?

Just a quick update. I am seeing some gain with the Lazy H now that the feed line exiting the antenna has been moved to a 90 degree angle, but I don't think I am seeing the 5.9 dbd gain promised in the ARRL Antenna Handbook. I would guess it is more around 3 or 4 dbd gain with 1/2 wave length elements and 1/2 wave spacing between the top and bottom elements. It seems like alot of trouble to go to when an extended double zepp at the same height as top wire of the Lazy H might do just as well if not better. The plus is the Lazy H may have cleaner nulls off the sides which is helping with the occasional AM carriers that are coming out of Central and South America.

It doesn't hop, per se, but it does pulse.

>
> Also, how is a field strength meter calibrated for emitted power with
> all the variables involved?

It isn't..

The field strength meter measures power density (W/sq meter) or field (V/m), and you have to figure out how that relates back to transmitted power.

The OP wasn't actually reading it in power, he was using the meter as a sort of transfer standard. i.e. say it reads linearly in relative power from 0-100. You put a known 1 W source at 10 feet, and it reads, say, 88.

You put your unknown at 10 feet, and it reads, say, 44, so you calculate that the source must have been 1/2 Watt.

The problem is that you're really making more of an ERP (Tx power + antenna effects) measurement assuming an isotropic source/meter, which can easily have 10 dB of error from a variety of factors.

I'll bet they're better connected than you think. Are there sheet metal screws joining them? what's holding the strips to the frame? Can you put a wire/foil tape under the screws. In any case, it would be easy to bond the panels together with some short jumpers. I can think of a variety of ways to do this, but one of the easiest might be a strip of copper foil tape along the 20 foot length. Sand the powder coat away on a spot on each "strip", run a stainless sheet metal screw through the copper foil or braid and the aluminum. Then glop on something to seal it so it doesn't corrode or leak. Butyl roof mastic might be a good thing.

A fancier way would be to get another aluminum strip and spot weld it.

You need to seriously think about bonding the roof anyway, so that is your best bet.

But, capacitively coupling from something lying on the surface would also probably work fairly well. Wide aluminum flashing laid out from your antenna base across the top of your corrugations (bend it to fit the ridges) and glued down might work pretty well.

If you had, say, 1 foot wide by 10 feet long, and it's 1/8" max distance, that's like a capacitor of about 500pF. Put a couple or three of those strips and you're doing pretty well. For your frequencies, it's like it's actually physically connected.

That makes sense. But, what about reflections, exact positioning, etc?
For example, in a low-signal location, moving my cell phone a fraction
of an inch can change the signal from "no connection" to two bars. In a
room with light fixtures, power wiring in the walls, picture frames,
computers, etc, I doubt the reading can be of much value. It might be
better to move the detector all around while recording readings to get
an average.

But, you know all that.

I tried to cancel my last post but it may not have done so.

In thinking more about it, I have to agree. Especially in light of your
allowance of the 10 dB.

So, in summary, excellent reply.

73,
John

> Urrrrgh

That's due to an FCC requirement. The FCC says (or used to say) that the antennas on consumer-type Part 15 wireless gear had to be "not commonly available" or words to that effect. Reverse-polarity gendering, reversed threads, etc. are all common techniques... and of course, as soon as one is used, it rapidly becomes so popular that it ceases to be "not commonly available" :-)

The specific intent was to try to discourage consumers from changing the antennas on WiFi gear. The certification of WiFi equipment is done on the system as a whole (radio + antenna), and changing to a higher-gain antenna automatically invalidates the certification and makes the WiFi system technically illegal to operate (at least, until it's re-tested and re-certificated with the new antenna).

If I recall correctly, the FCC modified the rules a year or two ago. A system's manufacturer is now allowed to test their system with one or more types of antennas, having different amounts of gain, and publish the gain number for the highest-gain antenna with which the system has been successfully certificated. It's then legal for an installer to substitute a different antenna than the original... as long as the substituted antenna has the same, or lower gain than the highest-gain antenna that the manufacturer has certificated.

These rules are, I suspect, honored far more in the breach than in the observance... and there seem to be very few manufacturers who go to the trouble of publicizing the "highest-gain antenna allowed with this system" information. That's probably going to be done only for high-grade commercial gear, not consumer-grade routers or the like.

Yes, there are various connections with sheet metal strips running across
all the channels, and a self tapping screw into each channel. There are
connections between everything, but a little uncertain as to the quality of
the connections.

And even the cheapest units on the market have MIMO. 59USD is the cheapest I have seen, but they could be cheaper.

For those that have never heard of MIMO it's a way of encoding more information on the same frequency by having multiple antennas spatially separated on 1 or both ends.

The upshot here is that once the unit has multiple antennas it not only can spatially encode it, it can also beam it.

Walt, you continue to amaze me with your apparently wonderful and extensive knowledge
with antennas and transmission lines. I look forward to finding threads where you have
entered a discussion on some topic or other. I have been a Ham since 1958. I've studied,
and read lots on the subject and always wished, but was never able to really understand the
aforementioned topics to any degree. I've built and played around with many antennas over the years.
Reading this newsgroup and many of the discussions has taught me a lot, but your ability to relate various
aspects which might to me be seemingly unrelated, and put them into words which are both meaningful
and understandable blows my mind. Your replies advising Michael on just this thread alone have been
great.

I've been meaning to say this for years -- now here it is --
Thanks for being around and sharing your goodies with us all.

One other thought, Michael, is that if you made the lazy-H with 1/2wl spacing for 20m and then use it on 10m, the spacing is now 1wl. I haven't seen any figures for that spacing, but isn't it possible that with that spacing the gain might not be what you expect? Especially if it works properly on 20m?

Hello, and moral issues aside for the moment, you'll probably discover very quickly that unlike a few years ago most, if not all, Wi-Fi access points/cable routers in your area these days are probably protected either by WEP (old) or WPA-2. (A Wi-Fi laptop with a network scan utility will usually indicate protected/open networks). And even many of those with older equipment have gotten wise.

The newer boxes usually have the protection turned on out-of-the-box with a password (changeable by the user/administrator). Older boxes had WEP turned off by default and a lot of users just plugged them in and never bothered to read the user guide and/or turn on the protection.
Sincerely, and 73s from N4GGO,

Hello, and I forgot to add that if your objective is to access public
Wi-Fi (which is usually unprotected) at a distance then have at it.
Sort of like stationary war driving. My previous comments pertained to
accessing private/home Wi-Fi nets. Sincerely,

Hello once more. One last thing to add is that even if one installs a high-gain Wi-Fi antenna, depending on the distance to the source, you probably won't have clear line-of-sight and subject to multipath problems. The network might show a "4 green bars" signal strength one moment and be yellow, red, or out the next). Sincerely,

I'm definitely using a less than scientific method, so don't take my
estimation as solid proof. It is just a guess at best.

This Lazy H is specifically made for 10 meters, the summer Sporadic E
season, and the steadily climbing solar flux. I almost never use 20
meters.

Thank you Irv, for the nice words you posted about me. I was fortunate to have been an antenna engineer with RCA for 31 years, where I was surrounded with professionals who were in the top echelon of antenna developers. I've had no other formal training in engineering other than my close association with them, and studying their voluminous text books. Learning as a ham (78 yrs continually licensed since 1933) is clearly the root of my engineering knowledge.

Do you have a copy of my book, "Reflections--Transmission Lines and Antennas? If not, some of the chapters from the book are available for downloading at my web page at www.w2du.com.

Thanks again, Irv,

Walt, W2DU

I used to have a 1 watt USB dongle, came from china ...

I am thinking you might still be able to locate one on ebay?

Anyway, let me know what you find. I am going to be setting up a long range link in the near future, for a friend.

Could the relationship between time and distance problem be impacting
performance? Every other influencing parameter appears to be a
constant. Lengthening the timeout on your end might provide a
solution.

Do you have a copy of my book, "Reflections--Transmission Lines and
Antennas? If not, some of the chapters from the book are available for
downloading at my web page at www.w2du.com.

Thanks again, Irv,

Walt, W2DU

Wow! Impressive resume Walt. It's funny you should ask about 'Refections'.
I never had the book, but did download
and study the available chapters from your website.

Due to some pretty serious illness and surgery during the past two years I
had to sell my house. At the same time my
prognosis was so limited that I gave away all my equipment, tools, parts,
and books -- most of it to other hams as well
as our local radio club. I had more antenna books than anything. We never
dreamed I would be in condition to operate
a station again and it wasn't easy giving up one of my great loves in
life -- HAM RADIO!

As per Murphy's Laws, my recovery was remarkable, but I had to move into a
seniors residence where nursing
assistance was available, and since then I have had restorative surgery and
am in pretty good condition again.
I am now ready to resume my participation in the hobby, but in a very
downsized manner. I just bought a
Yaesu FT-817ND (an all band/mode QRP rig, the only rig I ever bought brand
new) and am
in the process of building a magnetic loop antenna which I can cleverly
conceal on my balcony.
Basically it is a very simple project, considering the fact that I will be
operating either 5w or 2.5w
and do not have to go overboard on a HV tuning cap. I've always
been a low power operator, knowing that with a little operating skill, and a
'decent' antenna you don't need
a lot to have a bundle of fun. The snow has just cleared from my area
(Calgary, Alberta) and I should be up
and operating pretty soon (as soon as I can concoct a simple insulated
coupling between the tuning cap
drive motor and the capacitor). The principles of the magnetic loop are
simple, and I have been able to
download lots of good hints and kinks over the net -- more than I need.

So I'm a long way from dead, and looking forward to resuming the hobby which has kept me fully
occupied for many years.

I've helped many fellow hams with invisible antennas -- now it's my turn and I'm approaching it
with a very optomistic outlook. Starting over is not difficult -- once you have the knowledge, the
rest is easy. Maybe we'll meet around the bands someday.

Thanks again for all you've given to the hobby! Ohm's Law was easy, but we needed folks like
you for the antenna understanding.

Irv, VE6BP

I appreciate the reply, it seems my Alfa watt [bs-rating=
1/10 watt] is making the grade with 4 access points reliably
so it's just the little boy ego in me that seems spoiled when
110 access points are showing up and only a handful can hear
me. Then again it's real crowded here and channel bleeding or
some other 'Over crowded' phenomenon is dissing my male ego. I
sort of feel like a dumb truck driver running 1500 watts to
talk to the driver behind me9 In respect to the industry and
moral conscience I do not want to splatter my neighbors with a
gazillion watts and make their 5 bar connections slow because
of me and rf splatter. You guys know so much more then I it
isn't funny, don't want to sound like a moron but this "Dish"

theory is a hidden treasure right under everyone's nose and it amazes me that just putting a retired Dish Network disk 13" behind the Alfa USB WiFi with the 3 DB gain Vertical ground antenna on it gives me a 5 bar signal from what used to be a 1. The reason I am picking on this one AP is that I have the owners blessing to use it, so why not focus on the legal one. Sure I am willing to hack a stranger's one if I have to, but here is a case where I don't, so I won't. But up till now his signal was week, now it's good, but experimenting with the other unsecured AP's there are some that are 3 bars and can not get a handshake for more then 10 seconds at 1 MBPS Then PWAfffffffft!!! I am bumped off then on then off then on&#65533; Weird I say.
But it has all the symptoms of an Elephant base station, all ears no mouth, and I am Irish I don't take custom to things that way, generally the other way around LoL.
But I don't want to be a CB Rambo moron and ruin it for everyone else; I am on line at a steady 54 MBPS right now so why bother. Just Ego I guess or interest in the science maybe.
By the way the Dish is Indoors!!! I used to be a HAM, tech license but let it laps years ago. Can't stand the FCC's attitude.

Well I'm no Ham Pro but Network stuff I can help. You can USB to
the dish up to 75 feet BUT, you have to interrupt the line run
with a USB hub before you reach 30 feet, and for Geeky reasons I
don't understand I have been told that NEVER put the
interrupting USB hub evenly in the middle of a run. Sounds like
you need 2 hubs, each at about 25 feet of USB cable. Or; if you
can get to just under the roof in the attic use a HUB at 25
feet, and then a HUB at almost 30 more feet put a cheap Alfa
WiFi USB dongle or 1 watt model [about 70 bucks] Just under
the antenna, then run 10 feet of the 400 Microwave cable from
the Alfa to the feed horn of the dish. 3 db loss at ten feet. I
am using the 3 DB gain Vertical ground that is popular with the
Alfa USB dongle indoors so it's located AT the feed horn itself,
but in your case the semi USB to near the dish then a RF cable
short run for the antenna will keep the Alfa unit out of the
weather. The Alfa watt ratings are crap; I would do the 1 watt
model if you want at least 300 miliwatts out.
My watt model is struggling to be heard, so 3 bar signals it
can hear but the AP's can't hear me as well [I think].
Could be channel bleed though. If you wanted a lesson on FCC law
you would have asked so I wont go there [to much] and as you

know by my previous posts I don't care, but for your own good be aware you may be pushing the limits. Unlike me if you have a HAM ticket that could be a problem if you get caught. I'm not big on POWER drunkenness anyway, sensitivity and narrow RF beams make more sense and displays intelligence. And the challenge is fun ;-)

You indicated that you're working other repeaters with ease. Blaming
the trees sounds right.

I think a 2m beam is the way to go. I've used one at Field Day for
ten or so years from south of San Diego and easily worked 100 miles
into Los Angeles, simplex, obviously. The improvement in performance
is dramatic with 15 dBi gain, compared to approx 2 dBi gain of an end-
fed dipole, your j-pole. My two beams were less than 50 dollars
apiece at ham swap meets. Mount with elements vertical.

I just did an experiment and, as I expected, a 10 dB increase in
signal strength took me from unreadable to Q5 copy with tolerable
background hiss. (I used switchable attenuators to set up the signal
test conditions and a distant repeater as the test signal.)

If the repeater is no worse than "barely readable," 10 dB should fix
you up.

By the way, the gain effect is not so great that you'd lose the other
repeaters, unless one just happened to hit a deep null by bad luck.

"Sal"

Not only that, If he uses NO nails or drills NO holes for screws
he is not adding to the structure perminantly witch is a no no
[common sense]. I would use a series of clamps, and not leave it
up in bad weather or when I am away , seems as though temporary
would be a better aproach. I'm having alot of luck using mine
indoors LoL.

1369. Re: The Lazy H does not seem to exhibit any gain over a dipole in the real world

Newsgroup: rec.radio.amateur.antenna
Date: 2011-06-04 14:04:28 UTC
From: Michael <google@shadowstorm.com>
Message-ID: <7d740462-6aab-446c-8899-c699f5373f2f@x3g2000yqj.googlegroups.com>
Source record: 4670

Final verdict on the center fed Lazy H antenna for 10 meters...

I really wanted to like this antenna. I really wanted it to work as stated in the various handbooks. I have checked and re-checked the measurements, and I have double checked the connectivity to make sure the top and bottom elements were being fed in phase. The bottom left element was connected to the top left element. The bottom right element was connected to the top right element. I have done countless A/B/C test with a dipole, an extended double zepp, and the Lazy H all broadside to the same direction on 10 meters. This antenna was specifically cut for 10 meters, and it was installed for horizontal polarization as shown in the ARRL handbook at heights of 40 feet and 50 feet at the top wire. I double checked everything, but the final verdict is not what I had hoped.

Here it is;

In the real world on 10 meters the Lazy H antenna with four half wave elements on 10 meters (two collinear elements on top and two collinear elements on the bottom), half wave spacing between the top and bottom horizontal elements, center fed with 450 ladder line all the way back to the antenna tuner, using a 450 ohm ladder line phasing line to connect the top and bottom elements with no twist was consistently out performed by a 10 meter extended double zepp facing the same direction even when the Lazy H antenna was given a 10 foot height advantage over the extended double zepp. On many occasions the Lazy H was also out performed by the 10 meter dipole dipole. I have not tried the end fed Lazy H design with the 1/4 wave matching stub and the 180 degree twist in the phasing line.

On a positive note, the extended double zepp antenna with a 450 ohm matching section down to a 1:1 balun and then 50 ohm coax is a solid performer, and it consistently out performs a dipole and the Lazy H broadside to the antenna.

You are "matching" 450 ohm line to 50 ohm coax thru a 1:1 balun?

Where is the matchbox/tuner located?

Never mind, should have read your post closer, you are claiming to have
already handled it in the "450 ohm matching section."

probably because it is unbalanced by being connected:
>to the antenna tuner
which through its ground connection unbalances the Lazy H.

For the entire duration of your discussion, I've seen no treatment for common mode problems that you have described by various symptoms in the past. Your complaint of poor performance is a chief indicator.

Other indications have ranged variably from glaring beyond that to not apparent yet remaining a problem still, as is obvious by the poor gain performance for all variations.

You already have the solution in the other antenna:
> a 1:1 balun and then 50 ohm coax is a solid
>performer
provided the BalUn is a W2DU.

Your problem is NOT the antenna!

Merely *attaching* something to the non-Exclusive Use common
area of a condo property can be prohibited by the homeowners
association. It is like someone tying something to your car - he can
claim that it isn't a *permanent* attachment, but you'd be legally
correct in requiring its removal. The surface of a patio, on the other
hand, is *meant* to have things set on it, and so setting a tripod to
hold a dish cannot be prohibited on other than safety considerations
(and perhaps also on historical site considerations).

Suspend a heavy object from a rope over level ground. If I have plugged in the correct numbers, the repeater will be on a line drawn by the shadow of the rope at 12:55. That is, the repeater will be directly below the sun at that time.

Maybe you can get an idea of the path to the repeater that way.

Well, I have applied some numbers today and I am changing my mind that the trees are not the problem.

If my numbers are correct: The repeater, 19 miles away, is 1900 feet above his elevation. At that distance, the antenna will appear be about 240 feet lower than actual due to earth curvature. That makes the antenna appear to be about 0.954 degrees above the horizon.

That is equivalent to 60 feet at 3600 feet. In other words, 60 foot trees closer in will be completely in the way. The hurtful part of this is that his antenna at 45 feet will have a lowest angle of radiation (take-off angle) of .7 degrees, right into the near trees. The next lobe above that is at 2.2 degrees. Between those two lobes is a null.

In short, I think his antenna is in a null. I think the only answer for his present situation is to raise the antenna another 10 feet.

What do you think?

73,
John

Clever trick, but methinks I have an easier way. I've sighted 1
degree beamwidth microwave dishes this way:

1. Place a road map on a flat surface[1]. If you can't find a road
map, print a Google Maps or equivalent road map on a piece of
paper[2].
2. Pound a nail or push pin into the map at your location.
3. Find a distant mountain, that's also visible. Pound a nail into
the map at its location and sight between the two nails to the distant
mountain.
4. Without moving the map, find the distant repeater location on the
map and pound in a 3rd nail or push pin.
5. Sight from the nail at your location, to the nail at the repeater
location. What you see is where it's located.

[1] Yes, the earth really is flat.
[2] When I didn't have a printed map handy, I've used my laptop LCD
screen and 3ea flat head screws.

Easier than what I suggested? Actually, all he has to do is step outside at 12:54 and look at the Sun's location. (I admit it is more accurate to do this in the winter.)

Hello John,

This link:
http://www.tetech.nl/divers/Kirk_Repeater_USA_1.png
shows the path profiles with and without trees (from Radio Mobile,
VE2DBE). I will keep it there for some weeks.
I used 30m (98ft) high trees (so they are easy to see).

The trees cover some additional part of the first fresnel zone, but
the average canopy will be lower and the absorption loss is not that
high at 146 MHz.

So yes, there is influence from the trees, but not that much I think.
If you want to get some increase in signal, you need to remove lots of
them, and he don't want to do that. Note that the first trees are
160m away from his antenna (info from google earth, based on data
provided by Kirk).

With kind regards,

Wim

The tuners I have both have built in baluns. After I took down the
Lazy H I put up a delta loop with 300 ohm twin lead back to the same
balanced line tuner connections. The delta loop out performed the
dipole by a hair, but the delta loop has a height advantage over the
dipole.

I have some other baluns lying around. I suppose I could hook the
450 ladder line to one of those baluns and then connect a coax jumper
between it and the antenna tuner and try it. It seems like they may
be W2AU baluns. I bought them back in the 1990s, but I have not looked
at the labels in awhile.

I still may try the end fed Lazy H with the twist.

Michael

Well, your method only works at exactly 12:54PM, requires remembering
daylight savings time, requires dark glasses to avoid blindness, works
badly in fog, need to get it right the first time, and offers no way
to document the results. At 12:54PM, the sun is almost directly over
head with no point of reference, as you would have at the horizon.
Manually translating the sun's overhead direction, to azimuth at the
horizon, requires considerable guesswork. A plumb line might helpful.

Incidentally, trees are a very real problem with antenna sighting:
<http://802.11junk.com/jeffl/pics/DBS/index.html>
That's my view of the DirecTV bird at 101 degrees. The photos were
taken during the bi-annual solar outage, where the sun gets behind the
satellite belt.
<http://en.wikipedia.org/wiki/Solar_outage>
Note the branch shadows on the dish, which are blocking the signal.

>> [1] Yes, the earth really is flat.
>> [2] When I didn't have a printed map handy, I've used my laptop LCD
>> screen and 3ea flat head screws.
>
>I am afraid I cannot tell whether items [1] and [2] are just screwing

As far as this measurement is concerned, the earth is essentially flat
over fairly small areas. No spherical geometry required. Even the
United Nations has adopted the flat earth map for its flag.
<http://upload.wikimedia.org/wikipedia/commons/2/2f/Flag_of_the_United_Nations.svg>
Antarctica is a collection of icicles around the outer edge.

The 2nd item is for real. I was on top of a mountain, trying to aim a
dish without a map. I had Street Atlas USA v5 on my then ancient
Toshiblah 100CS laptop, which I used for my initial bearing. Other
than having a difficult time holding the laptop, problems viewing the
screen in the sunlight, and too short a base line, it worked.

>By the way, Jeff, you have a great deal to offer the group by way of
>your vast experience. If I have been disrespectful of that, then I

Thanks and not a problem. You have a long way to go before such
comments become a problem.

I just remembered most of those external baluns are 1:1 baluns. I do have one external commercial 4:1 balun, and one 4:1 balun I hand wound from a schematic in one of my antenna books.

A net book and managable wireless switch running a stable
version of Linux might work,
But a programmable router would be better, especially one that
has a Linux os and is Hackable. Here is an interesting video
that makes a run of the mill Lynksys 80 dollar router do what a
Cisco AirNet 2400 can, Repeater and all, they hack the OS and
install their free to public home brew features.

http://www.youtube.com/watch?v=08eVqpPVGiU

So much for spending 600 bucks if it works, you'll be under a
hundred.
Personally I am lazy and employed; I would just go out and buy a
Cisco or other top end product and be done with it.

A separate computer running at the base of a big antenna? I
wouldn't want that on a cold winters night and the snows coming
down etc...

That is most likely where my problem is. Remember this is just
a redneck style Git'r done solution till my commercial one
arrives, a vertical anttenna in front of a dish has got all
ears and no mouth written all over it.
Now if I was using a feed horn [cantenna type] well that would
prove tx power and your sugestion as well is the culprit, we
know the clutter thing is in there because this whole shmoosh
is indoors. I hate running high power $$$ and frequent
burnouts of the finals. I like to think a half watt is all
I'll need. Now if I can get my TX to look like a Laser beam
hey hey.

Seriously check this out;
www.youtube.com/watch?v=piFISJKyV6c
www.youtube.com/watch?v=weEZtBTfEMU

The software is free but I preffer the USB dongle os
running BackTrack 3 It's a bit simpler, and you need 2 wifi
dongles, prefferably the Athros as suggested, II use them on
other versions of Linux too, they seem to be the best for
hackin around, they are permiscuos and can Inject packets to
an already busy data streem thanx to the MAC address
spoofabilty they have.
You can also use this software to turn a laptop with two
dongles into a covert repeater. But expect downtime with that
idea.
You can Cache everybodys WEP keys buy faking your IP as one of
the AP points in the Air. Send all 'packets copy' to a data
BIN folder and run the desypher software built in to get the
wep, wpk and such. Even SSL ports. It's my job to keep these
script kiddies out of my network, I have to know this stuff.
Our wireless Credit card system is constantly under attack
by NIX kids [wannabe hacker teens running linux] As long as I
can crack it, they will not use it, it's sitting there off

line collecting dust per order ME!! WEP is not safe neither
is WPK, though a data base dictionary service is needed for
WPK sometimes for 25 bucks these hackers will take your glop
of ssl data and within 1 day send you the security key.
This is the nightmare behind CLOUD computing, the access to
several hundred micro proccessors to crack a key is now CHEAP,
I use 40 lab machines to convert and crunch a DVD 2 hour video
in ten minutes with cloud computing software. It's realy FARM
computing not quite the same as the term local ads are running
such as google is now cloud computing.
Unfortunatly Criminal minds are more intrested in this more
then we are.

http://www.youtube.com/watch?v=08eVqpPVGiU

So much for spending 600 bucks if it works, you'll be under a
hundred. Only 235 milliwatts max though.
Personally I am lazy and employed; I would just go out and buy
a Cisco 1/2 watt or other top end product and be done with it.
Can't use a whole watt if you woryy about FCC dudes lurking
around, that and a 30 db gain your way over limit.
Too bad these little routers do not support PoE [Power over
eithernet, you can use a power injector [40 bucks] to send the
power to the router through two of the 6 conductors of the
CAT5 cable.

For now just run a cat 5 cable and low voltage power supply
bell wire to the router witch HAS WiFi 2 channel built in.
Check and make sure there are External Antenna outputs on this
otherwise walk away from it. Soldering 2.4 GHz equipment

___s#$ks. If I didn't own a 1300 dollar wire bonder unit I
wouldn't try it, but fortunately I do and the job still stinks
, If your not a neat freak with connections you have sporadic
rf leaking everywhere.

google 'network stumbler' , it's freeware or actually "BEG"-ware
but it works most the time.
I here there's a few WalMart craptastic USB dongles that will
not work with it but thats a rare synptom.

Be extreeeeeeemly carefull here, I know you said DC load tested the antenna but was it unplugged? More then once in my younger dumber days I sent the voltage comming out of the Volt meter [digital] hap hazardly into the final output of the radio, that was more then enouph to poof the transmitter chip, now it's toast. I would never believe the amp/volts comming out of a small digital test meter would roast the finals, but it did.

The insanity of it being a crime to receive any radio signal is so
obvious, I can only consider those recognize it as a VALID crime are insane.

However, I have always felt the same, and since a VERY young age, that
making the growing or possession of plants a crime demonstrates EXACTLY
the same brand of insanity.

If you look around, you will find other examples of this same insanity ...

The insanity of it being a crime to receive any radio signal is so obvious, I can only consider those recognizing it as a VALID crime are insane.

However, I have always felt the same, and since a VERY young age, that making the growing or possession of certain plants a crime demonstrates EXACTLY the same brand of insanity. The men/groups/etc. establishing themselves as rightfully being able to command such insanity must think themselves GOD, how nice!

If you look around, you will find other examples of this same brand of insanity ... and, if you look even closer, you will find it usually involves a law which allows some to become very rich from its' enforcement ... so that in the end, those having the laws forced upon them are forced into participation in the insanity! As, even the simply actions to resist those laws, and even solely on principal, brings one under great scrutiny, or even punitive actions! And, this seems to have a 1:1 correlation to the "money stream(s)" generated by the law(s.)

But, has little to do with lossy coax at high frequencies ...

The answer is diversity reception, so you don't get nulls where signal is
lost.

In that case, perhaps it is due to his antenna being at a height that puts the target into a null. Along with low repeater output power, I suppose that could cause it.

Thanks, Wim.

>from a schematic in one of my antenna books.

Hi Michael,

The odds are that the BalUns you wound are similar to the ones in your tuner(s) - and they will NOT do the job properly.

By properly, the BalUn MUST choke the line. This comes for free with the W2DU style, as there is only one way to build one, the right way.

The distinction is between what are called voltage BalUns and current BalUns. Frequently, web sites that purport to know the difference DON'T know the difference. The W2DU BalUn is an example of a current BalUn with a 1:1 ratio. It is also a choke. Very few BalUns that are published on the web are current BalUns. Similarly, very few have the necessary choking action.

One solution is to feed a W2DU BalUn, that in turn feeds any BalUn with the required transformation ratio, that then in turn feeds the antenna. The W2DU BalUn takes care of the proper choking action needed. However, this may not work with the internal BalUns found in nearly every tuner on the market. (How does one insert the choke to an internal BalUn?) Problem here is that if there is ANY path to ground that goes around the choke, you have just made it an exercise in futility.

And lastly, you have described a number of problems with the antenna that were both inside and outside of the focus of gain. ALL were functions of Common Mode currents. Choking the line is the best all-around solution.

Okay. I take that back. I just ran a simulation with EZNEC and it shows twice as much uV available at the receiver than Radio Mobile, so my conclusion is that a pattern null is not involved. I'm stumped.

Many systems that include a need for portability with something approaching
continuous coverage need to use diversity reception to achieve this. The
problem of nulls at these frequencies is quite bad, as we all know when we
try to use mobile phones..It only works if I stand on a chair and raise my
right leg, syndrome.

Brian

Or do what I do. Mount it on a tripod and aim it so you can shove two
legs again the rail and hold it place with a bungee chord. That makes
it a breeze to take in and put up.

You could make a sort of customized fixture, too, that "mates" with the railing, so that you just sort of click it into position, and it's automatically aligned properly. A piece of wood with notches that align with the vertical rails, for instance. If you want something more weatherproof than wood, a polyethylene cutting board makes a great material to work with. Easy to cut, indestructible, etc.

Velcro is also your friend. A strap with velcro to snug it up against the rail would work pretty well. Much faster than some sort of clamp scheme, typically, and less likely to arouse the ire of a landlord who doesn't want clamp marks. (any sort of screw clamp is inevitably going to loosen, or be over tightened, etc.)

Mount it atop a refrigerator unit, on the porch, use the refrige to keep
your beer in -- no one could ask you to remove that from the porch!

Update on the 10 meter Lazy H...

I did a little reading on ladder line at the web page below;

http://www.athensarc.org/ladder.asp

and then in the ARRL handbook.

With the knowledge gained form the two sources I made the following changes;

I changed the length of the 450 ohm ladder line feeding the antenna to make sure it was not a multiple of a 1/2 wavelength at 10 meters, and the antenna tuner was able to tune the Lazy H more easily. I also suspect there may be a problem with the balun in the Dentron MT-3000a tuner. When I hook up the Drake MN-75 tuner with the internal 4:1 balun I hand wound myself I am seeing gain from the Lazy H antenna in it's preferred direction compared to the dipole, but when I switch to the Dentron MT-3000a I am not seeing gain when I compare the dipole to the Lazy H. I think I am going to remove the factory balun from the Dentron MT-3000a and hand wind a new 4:1 balun for it.

I did some searching on the Internet concerning the use of the Dentron
MT-3000a tuner and using the balun for 450 ohm ladder line on10
meters, and I found the following post from K8JS on a eham.net review
of the Dentron MT-3000a tuner..

Below is K8JS's post on eham.net...

==========
K8JS Rating: 3/5 Feb 22, 2004 00:59 Send this review to a friend
Basically Is OK, but not the best Tuner Out There Time owned: more
than 12 months

...<snip>...

I also ran balanced feedline antennas at that time, and discovered
that the built-in balun was badly UN-balanced at it's "balanced" port
for 10 thru 20 meters.
To help remedy that problem I had to replace it with a physically

larger, and much superior "Super Balun" from Palomar that barely physically fit within the tuner's chassis.
So - with correcting the coil's grounded end making a better contact to the chassis, replacing the unit's inferior balun, and gingerly operating those flakey rectangular switched, I was able to continue to use that otherwise very nice tuner for several more years. ---John, K8JS

==========

Well, looks like it is time to replace the stock Dentron MT-3000a 4:1 balun with a home made one.

>Another silly idea?

Bad idea. It might work in transmit, but in receive, all you're going to hear is the broadband noise coming from whatever data is moving on the ethernet pairs. There is some isolation between the CAT5 wire pairs, but not enough to prevent noise coupling entirely. Even if you borrowed and isolated one of the two pairs used for 802.3af and 802.3at for the antenna, you would still experience considerable noise pickup.

"When all the bad ideas have been eliminated, whatever remains, no matter how improbable, must be a good idea."
(Me, in about 1980 during a design review)

>Is it a silly and dangerous idea?

If you mean using the power line for part of an antenna, and the earth ground (through the power lines) as the rest, it's both dangerous and impractical. One mistake in wiring an you have a fried customer. The impedance of this contrivance is also indeterminant and non-constant, making matching both a transmitter and receiver difficult and expensive. The low impedance of the ground loop (almost a short circuit) is going to be difficult to match at both 1MHz and 100Mhz. There's also an amazing amount of RF noise present on the power lines, which your AM/FM receiver is not going to appreciate.

In the distant past, I recall some vendor adding a 4th wire to the power cord, and using it for an antenna. It worked when there was fairly clean power, but failed badly if there was a noise generator (usually motors) on the line.

Back in the early 1960's, I got my childhood start in electronics when I read an advertisement in Popular Electronics(?) for a power line adapter to "Turn Your House Wiring into a Giant 1000ft TV Antenna". Inside the magic box was a "capacitator", which coupled the twinlead antenna terminals to the AC power line. It didn't work, but I didn't know that. This was in the days of AC/DC radios and TV's, with no AC transformer isolation. I was saved from a premature demise by reversing the power plug to see if it would improve reception, and blowing the main fuse.

Not so dangerous or silly, in all reality.....

Apparently you have never heard of "Carrier Current Transmissions"....
Back 4+ decades ago, I was Chief Engineer of a College Campus Student
run Radio Station, that used the Campus Power Distribution System as the
Transmission Line and Antenna for our AM Broadcast operations. Each of
the Systems transformers in each building was bridged with .1 uf 10,000
Vac Capacitors to conduct the RF around them and into the buildings. All
the Distribution was done via buried Metal Conduits, which acted like
coax, and kept our "Over the Air" Signal Strength within FCC Part 15

Limits at the time. We used a 100 Watt Transmitter coupled into the Secondary of the Main Campus Feed SubStation Transformer, which was in an Basement Vault, in one of the Campus buildings. Worked just "Spiffy" and we were even inspected by the FCC yearly and were in compliance with all FCC Rules and Regulations for Part 15 emissions, in place at the time. Same basic concept is still used today, by the X10 System of Whole House Control Systems, and by the Ethernet over PowerLine Adapters that are in use today. Not Magic, just plain OLD Technology at work.

Touche. I helped build the initial FM station and later the AM carrier current system while a student at Cal Poly Pomona in the early 1960's.

The key component was a ferrite transformer, that would pass 1MHz RF, but not 60 Hz AC. I forgot the name of the vendor. There was one central transmitter, a power splitter, coax cable to each of the dormitory buildings (because each had separate power xformers), and a ferrite transformer RF coupler to the building power lines. It worked, but student that were accustomed to the FM (mono) quality were disappointed with the noisy AM signal. I vaguely recall that it lasted about 5 years after I left.

Other than running underground cables, dealing with building inspectors, and handling listener complaints, I didn't have much experience with the carrier current AM hardware. It worked, for AM.

However, the author also wanted FM, presumably for an AM/FM receiver. Transmitting carrier current AM is one things, receiving is another. For entertainment value, put a small value capacitor between the antenna terminal of your receiver or spectrum analyzer and the power line. Yes, it will be mismatched and lossy, but good enough to demonstrate the large amount of noise found on the power lines.

Carrier current ethernet (HomePlug) does a decent job of moving data through such noisy lines by using broadband techniques 2-28Mhz for HomePlug AV, 2-50Mhz for IEEE901, and more for HomePlug AV2. With such lavish bandwidth, communications frequencies can be dynamically adjusted to use only those frequencies that aren't being clobbered by noise and interference. That can't be done with broadcast AM/FM, where each station is stuck on a specific frequency.

The only people that claim that X10 works are those that haven't used it. I have quite a collection of X10 and BSR modules sitting in a box somewhere. The problem is that X10 is a one way protocol. You send, and hope that something happens at the other end. No handshake, no error recovery, no reliability. I've used it in various locations with disgusting results. X10 also doesn't communicate audio, but various "wireless" intercoms that use the same 120Khz carrier

frequency. I also have a few of those stored, after I became tired of the line noises and buzz it would belch.

You do have a point, that is possible to use the power lines as an antenna or communications media safely. However, judging by the quality of the original question, I suspect that the OP might not be very well versed in how to do it safely.

I'll buy whatever you have.

I've been using it for 20 years or so, maybe more, not sure. Doesn't miss a beat. It depends on how you use it. Don't try to control things on other phases/other side of 220.

Similar to the issues with building BPL where you need to feed all phases. BTDT too. And in-building BPL, at least as built by Motorola in the mid 2000's, doesn't make much more than S9 even if the coax feed is connected directly to an amateur receiver, so is ham friendly. It may no longer be so, no data available after 2006 for me.

Sure. I'll collect what I can find and send you a photo. We can
haggle later over the price (i.e. anything that covers the shipping).

>I've been using it for 20 years or so, maybe more, not sure. Doesn't

There are tuned xformers to couple the 120Khz to different phases.
<http://www.smarthome.com/4820X/X10-XPCR-X10-Signal-Coupler-Repeater/p.aspx>
(You might find some of the user comments under the above URL rather
enlightening).

Sometimes, there's enough coupling between phases for it to work
without the xformer or repeater. Unfortunately, the places where I
tried to use X10 boxes were plagued with noisy power lines. Some of
it was the fault of the power company, which was eventually fixed
years later. The rest were HVAC motors, an electrostatic dust
precipitator, and oddities such as a negative ion generator, electric
shavers, and a noisy neon sign. I made the X10 work by programming
the controller to repeat all on/off commands 4 times, but that didn't
work with dimming or toggled outputs. After having someone slip and
fall in the dark, because the X10 system failed to turn on the outside
lights, the system was pulled and replaced with one that was hard
wired.

>Similar to the issues with building BPL where you need to feed all

>is connected directly to an amateur receiver, so is ham friendly. It
>may no longer be so, no data available after 2006 for me.

That would be the MU (Multi-Unit) system.
<http://www.netlinkweb.com/solutions/motorola/BPL-applications/BPL-MU.asp>
I have no experience with that one. Did you look at it on a spectrum analyzer? Motorola is one of the few BPL vendors that supplies devices that intentionally filter out "sensitive" bands, such as ham radio. My understanding (possibly wrong) is that since the entire building shares the same wiring, the bandwidth per user is limited during peak times.

User manual (9MB PDF):
<http://motorola.wirelessbroadbandsupport.com/software/sw_downlink_public.php?id=80806d75ff44060653d82a6204a05462>
See Pg 43 for the Bandwidth Manager settings. 42.5Mbits/sec maximum for the entire building.

Pg 54 has something called Power Spectral Density, which include mention that the power output is +22dBm (160mw) per carrier(?) for US rules, but can be cranked up considerably higher. With 84 channels, that's quite a bit of RF. Are you sure it's not a noise generator?

Pg 55 has the frequency chart, including notchos.
4.5-21Mhz, with notches at 5.5, 7.3, 10.3, 14.2-14.6, and 18.2Mhz. If you tested at 40 and 20 meters, you probably wouldn't have heard anything. Oddly, the notch at 18.2 should have been 18.1 for the 17 meter ham band.

Pg 78 shows how the user can monitor and set the frequencies in use.
It includes the comment:
"Grayed out values are reserved HAM radio frequencies and cannot be adjusted."
which may explain why you didn't hear much.

There are some interesting graphs starting on Pg 110.

1420. Re: The Lazy H does not seem to exhibit any gain over a dipole in the real world

Newsgroup: rec.radio.amateur.antenna
Date: 2011-06-08 12:54:49 UTC
From: Michael <google@shadowstorm.com>
Message-ID: <2b29207c-71ea-42ed-90fd-27046bb21d11@e21g2000vbz.googlegroups.com>
Source record: 4621

Woohoo! The center fed Lazy H is now working with gain in it's most favored directions, and it is now consistently out performing the dipole. I had already pointed the extended double zepp in another direction, so I'm not sure if the Lazy H is out performing the extended double zepp.

Below are the following real world lessons I learned from building the Lazy H wire antenna in the real world. Hopefully it will save future builders some time.

1) Make sure the 450 ohm ladder line exiting the center of the Lazy H back to the antenna tuner goes away from the Lazy H at a 90 degree angle for at least a full wavelength or more or it will skew the radiation pattern of the antenna.

2) Cut the 450 ohm ladder line going back to the tuner to a length that is NOT a multiple of a half wavelength on the frequency (or frequencies) you plan to use the antenna on. In my case since I only plan to use the Lazy H on 10 meters I found the length required to get back to the radio room, and then I added length until the total length landed in between multiples of a 1/2 wave at the antenna design frequency. The antenna tuner was more easily able to tune the Lazy H once I did that. When I measured the total length of the ladder line feeding the Lazy H I included one half of the phasing line that connected the top and bottom elements.

3) Do not allow sag in the ladder line back to the antenna tuner where the exiting ladder line falls close to the bottom half of the 450 ohm phasing line that is used to connect the top and bottom of the Lazy H or the SWR reading will go up noticeably.

4) The setting on the antenna tuner where a lowest SWR is tuned may not be the same setting where the receiver receives the strongest signal from the antenna. This quirk may be specific to my Dentron MT-3000a tuner and it's internal factory balun.

5) Following number 2 above will probably avoid this situation, but if your antenna tuner is unable to match the Lazy H at any setting change the length of the ladder line feeding the Lazy H.

Dear Michael KS4HY: Thanks for the up-date. You have indicated some ways to deal with the issues you encountered.

To emphasize what others have said: The issues you encountered would have been attenuated with common-mode chokes being used at feed-points (and perhaps at strategic places farther along).

1422. Any ideas on the screen reflector size for a Lazy H antenna?

Newsgroup: rec.radio.amateur.antenna
Date: 2011-06-08 14:37:38 UTC
From: Michael <google@shadowstorm.com>
Message-ID: <6f64fbed-842b-403c-99c4-9c72709f4344@p23g2000vbl.googlegroups.com>
Source record: 4623

I've noticed several sites (and books) show screen reflectors for various multiple driven element broadside arrays, but I have not seen any dimensions given for a screen reflector. I am aware that a parasitic reflector for a yagi is about 5% longer than the driven element. Is the same true for a screen reflector for a broadside array like the Lazy H antenna?

For instance, since the total length for the two top horizontal 1/2 wave elements in a Lazy H are generally 1 wavelength long plus the width of the center insulator does that mean a screen reflector should be roughly 5% longer than the total side to side width of the Lazy H antenna? Also is the best spacing between the Lazy H and the screen reflector the typical 0.2 wavelength shown for a Yagi beam antenna driven element and the parasitic reflector? If not is there a formula for determining the width and height of the screen reflector as well as the spacing between the Lazy H and the screen reflector for a broadside array like a Lazy H?

Thanks,

Michael Rawls

Screen reflectors aren't critical in terms of size.. bigger is better,
of course, and there's some sort of point of diminishing returns, but
basically, it's providing some approximation of a "infinite perfectly
conducting plane"... Sort of like a counterpoise for a vertical monopole..

Now, one could greatly reduce the amount of wire needed at the expense
of bandwidth, etc., by putting a tuned reflector in, as you've noted.

In what universe does a hard shutdown cause a head crash?

The reason you don't want a hard shutdown (other than spyware
having to flush everything it has gathered out the network
interface) is to make sure everything gets written to disk.

Painful to lose the last few seconds worth of disk updates,
perhaps, but far from a head crash.

And, yes, remote management consoles are useful.

You should always use the tuner setting that provides
an acceptable match using the least amount of inductance.
"coil turns, or wound inductor tap setting".
I think you will find that the settings that provide the
least loss, and yes, the receive noise is one way to gauge,
will correspond with the settings using the least inductance.
And the match doesn't have to be a perfect 1:1.. As long as
the rig will put out full power, it's good enough.

I looked at it band by band for the US amateur bands. I believe I also check out of band here and there, but it was 5 or 6 years ago. And that was straight from the transmitter level with a 1 meter cable and a 75 to 50 ohm mismatch.

I also swept our area 30 to 30 on HF with a not great hunk of wire and heard nothing beyond the normal ethernet, PC, printer and other office furniture. But nothing from the BPL which had a noticeable pattern.

Shared bandwidth is an issue, but it is also split up by phase, and that helps somewhat.

1428. Standing waves on antenna, doubts!

Newsgroup: rec.radio.amateur.antenna
Date: 2011-06-09 06:06:00 UTC
From: Camelot <scosmo@tiscalinet.it>
Message-ID: <db56c7b5-fbd4-43e2-a9cb-c1f276478ce2@m40g2000vbt.googlegroups.com>
Source record: 4629

Hello, I have some doubts about standing waves on antennas that I hope you could clarify!
As far as I understood, in a generic transmission line where we want only carry power from a source to a load, we need to cancel the reflected wave by adapting the load with the impedance of the line. The result of this operation is S11=S22=0 and VWWR=1 that means no standing waves.
As far as I understood, in an antenna we want to also avoid standing waves by having VWWR=1 in order to avoid overloading problem to the power stage...
From theory I know that the best radiating condition for an antenna is when it resonates, that is, when there is a standing wave… is that correct? How this condition is compatible with a VWWR=1 (no standing waves) for a good antenna matching? Is there something that I'm not catching?

Regards,

Camelot

I don't know that I'd say that "the best radiating condition for an antenna is when it resonates," necessarily. But certainly a resonant antenna is one that will have standing waves on it when it's excited.

However, the standing waves on a resonant antenna result in radiation by the antenna, and the result of the standing waves, the radiation, and the resonance is that the feedpoint of the antenna looks like a resistance that absorbs power. The exact resistance depends on many things, but in general it's a resistance that either directly provides a good match to a transmission line, or else can be matched to a transmission line with a few components.

By the way, it's also not necessary to have the antenna matched to the transmission line: although a particular line with standing waves delivering a certain amount of power to a load has more loss than the same line delivering power to a matched load (no standing waves), the additional loss from the standing waves may not be a big issue. In fact, it may be better from a lost-power standpoint to use a higher impedance open-wire line with relatively high standing waves, than to use a low impedance line (e.g., coax) with low standing waves, because the loss in the open-wire line can be very low. There are lots of other factors to consider, too, but the point is that you shouldn't assume that it's necessary to get the lowest possible SWR on the transmission line.

Let's take one more step back from this problem. The antenna, whether resonant or not, presents some impedance at its feedpoint. The purpose of the transmission line is to couple power between a transmitter and the antenna feedpoint (or from the antenna feedpoint to a receiver). You don't need to know what's actually going on in the antenna, you only need to know that feedpoint impedance, to select the proper transmission line and possibly a matching network between the line and the antenna's feedpoint. (Well...you also need to be aware of how the metallic conductors of the transmission line may upset the fields around the antenna and possibly provide for decoupling the feedline from the antenna's fields, but that's separate from the issue of coupling power between the antenna and the transmitter/receiver.)

Keep the details of how the antenna does its job--how the current is distributed on the antenna's conductors--separate from how you get power to and from the antenna, and you should be OK.

Cheers,
Tom

Hello Camelot,

Resonance in the antenna is not required for producing RF radiation.
Horn shaped structures and flared transmission lines are good
radiators over frequency ranges that can be over 1:5 (for example 1
GHz to 5 GHz). These wide band antennas rely on travelling waves in
their conductors. When the wave goes from the feed point towards the
end of the structure, it gradually attenuates because of the lost
energy due to (desired) radiation. The distribution of the current in
the antenna's conductors (amplitude and phase) determines the
radiation pattern.

Antennas made from thin wires show inconvenient impedance, except for
some special lengths. The best-known example is the halve wave center-
fed dipole. It gives a good match to coaxial transmission lines.
Though it has a good match to a 50 Ohm line (so no standing waves in
the transmission line), there are standing waves in the antenna. The
sinusoidal voltage and current distribution in a half wave dipole is
because of the large VSWR inside the antenna itself.

So the halve wave dipole fed from a 50 Ohms line shows high SWR in the
antenna, but low SWR in the feed line.

The full wave dipole is also in resonance (two end-fed halve wave
antennas), but its impedance is in the several hundreds Ohms to kOhms

range (depending in wire thickness). It has somewhat more directivity then the half wave dipole, but gives large mismatch to coaxial transmission lines. If you drive the full wave dipole directly from a coaxial line (and do the matching in the shack), you will very likely lose most of your transmitting power (in the form of heat in the coaxial feed line).

The full-wave dipole can be fed from an open wire transmission line (ladder line) directly. There will be mismatch at the antenna-feeder transition, but it will be less (ladder line has high char. Impedance). As Tim said, the loss (or attenuation) of the ladder line is significantly below that of coaxial transmission lines, so even high VSWR inside the transmission line will not lead to significant line loss.

Short antennas (length < 0.1 lambda) are good radiators, but their impedance can be so weird that it is impossible to match them to a convenient impedance without excessive loss. The losses are in the matching networks, not in the radiating structure itself.

So generally spoken, resonance (that is ohmic antenna behavior) is not required for an antenna to radiate.

Regarding transmission lines.
Zload = Zcable, is not required for long lines, but gives the lowest loss. Depending on your requirements, you may accept some mismatch between load and line (so standing waves in the line and somewhat increased line loss). Ladder line (parallel wire transmission line) can be used with significant SWR inside the line with relative low loss. The same SWR in a coaxial transmission line with same length may result in too much loss.

Transmission sections are used in matching networks. Well-known example: quarter wave transformer. It does function because of a standing wave part inside the quarter wave line.

Regarding the PA.
The PA just wants to see a certain load impedance to operate properly. With "properly" I mean delivering the stated power without too much stress on the PA's components.

With kind regards,

Wim

On Jun 9, 1:06 am, Camelot <sco...@tiscalinet.it> wrote:
> Hello, I have some doubts about standing waves on antennas that I hope
> you could clarify!

Please forgive the unfinished posting above. It happened without any
action on my part.

First of all, one needs to get one's nomenclature correct. Antennas
like single-wire dipoles and full-wave loops are Standing Wave
Antennas. Standing Wave Antennas always have standing waves on the
antenna. They may or may not have standing waves on the transmission
line.

The 50-75 ohm feedpoint impedance of a 1/2WL dipole is a virtual
impedance, the result of forward and reflected waves superposing into
standing waves on the Standing Wave Antenna. The SWR on the 1/2WL
antenna wire is approximately 20:1. Only about 20% of the total energy
in the RF waves on a 1/2WL dipole is radiated. If 100 watts is being
delivered to the antenna and ~100 watts is being radiated, there is
about 500 watts of joules/second stored on the antenna wire during
steady-state.

Maximum power transfer to the antenna occurs when the antenna *system*
is matched but it is not an impedance match. It is instead a
conjugate match. A system with an SWR of 10:1 on the ladder-line may
(or may not) be a near conjugate match. If it is a near conjugate
match, maximum *available* power will be delivered to the antenna.

To summarize: Standing Wave Antennas, like 1/2WL single-wire dipoles,
require standing waves on the antenna wire.

A flat system, e.g. 50 ohm coax to a 50 ohm antenna, is an impedance
match but it is also a (trivial) conjugate match. In a low-loss
system, a Z0-match guarantees a near conjugate match at the antenna
feedpoint.

A low-loss system with tuned feeders is a (conjugately matched) system
if the impedance looking one direction in the feedline is very close
to the conjugate of the impedance looking in the other direction.

When a Z0-match to 50 ohms is achieved by a tuner (or other network) a
near conjugate match is achieved in a low-loss system. In general, all
low-loss systems that are transferring the maximum amount of available
energy are matched, by definition, i.e. they are a near conjugate
match.

The reason that I say "near" conjugate match is that the conjugate matching theorem doesn't allow resistive losses in the analysis. Of course, there is no such thing as a lossless system in reality.

Exactly. Standing waves are often our friend. When one feeds a 1/2WL dipole with 1/2WL of ladder-line on 80m, one is depending upon the standing waves to transform the impedance looking into the feedline to the same value as it is at the antenna feedpoint. Without the standing waves on the 300 ohm matching section, a G5RV would not work. The transforming characteristics of a 1/4WL matching section depends upon standing waves. The proper functioning of stubs depends upon standing waves.

Cecil:

Don't even ask such a silly thing, happens all the time, here.

I just highlight, and then right click the post, of mine, which is in error. If using thunderbird (and I think you are), a menu will pop up, look near the bottom and find "Cancel Message", choosing that will create a popup which will ask you to confirm your wish to delete the message ...

Good luck ...

Well, maybe you're right. Lets's do the math.

On Pg 54, Motorola says the power spectral density is about -50dBm/Hz.
If your receiver was set for SSB with about a 3KHz bandwidth, that's:
-50dBm/Hz + 10log(3000Hz) = -50 + 34.7 = -15dBm
You should have been able to hear that when directly connected.

Assuming S9 is 50uv into 50 ohms, that's
P = E^2/R = (50*10^-6)^2 / 50 = 125 uWatts = -9dBm
You should have seen noise at 6dB over S9 on your guess meter
(ignoring the 50/75 ohm mismatch and ham radio band notch filters).

>Shared bandwidth is an issue, but it is also split up by phase, and that
>helps somewhat.

Good point. However, even commodity DSL (1.5Mbits/sec) download is
considered old technology by many broadband users. With 42.5Mbit/sec
aggregate bandwidth, that would minimally supply 28 typical
residential customers at 100% utilization, about double that if
overloaded, and maybe one user doing file sharing. Splitting phases
will increase that by x2 or x3, assuming there's no crosstalk between
phases. That's more than adequate for residential service, assuming
the building owner wants to pay for a T3 line or one third of an OC3

plus service.

I found 3ea X10 lamp modules and one controller. There are more
buried somewhere.

>Hello, I have some doubts about standing waves on antennas that I hope
you could clarify!
As far as I understood, in a generic transmission line where we want
only carry power from a source to a load, we need to cancel the
reflected wave by adapting the load with the impedance of the line.
The result of this operation is S11=S22=0 and VWWR=1 that means no
standing waves.

"VWWR=1 means no doubled voltage.

As far as I understood, in an antenna we want to also avoid standing
waves by having VWWR=1 in order to avoid overloading problem to the
power stage...
>From theory I know that the best radiating condition for an antenna is
when it resonates, that is, when there is a standing wave? is that
correct?

Standing wave is if the electrons reflects from the end.

> How this condition is compatible with a VWWR=1 (no standing
waves) for a good antenna matching? Is there something that I?m not
catching?

You simply do not know Tesla's discovery. Transmitting antennas are the
electrons guns.

In poor antenna the voltage is doubled (at ends) and you have the standing
waves.
In perfect antenna electrons jump off from the ends of a dipole and the
voltage is not doubled.
Of course Tesla's antenna radiate the alternate electric field.

Doubtful it would work at all. Most CAT5/CAT5e/CAT6 cable is shielded
these days so it wouldn't make a very effective radiator.

Not in the Peoples Republic of California. I use quite a bit of CAT5e
and some CAT6 and NONE of it is shielded here. In some countries
(i.e. Switzerland) shield CAT5 is required. The only place I see
shielded CAT5 is in industrial installations (high noise environment),
and in some ham stations (RFI proofing). I've also used gel filled
direct burial CAT5e which comes with a foil shield for the same price.
The connectors are a bit more expensive, but I figure it can't hurt,
especially when it's sharing the conduit with who knows what signal
cables.

Most of the shielded CAT5 systems I've seen do worse with shielding
than without. The problem is that the shields are usually grounded at
both ends, creating the potential for a ground loop. I use SNMP
statistics from the managed ethernet switches to determine if there's
a problem. Isolating one end of the shield usually fixes it.

Something else to think about that may help you understand:

Realize that if you connect a section of transmission line with one
impedance to a section with a different impedance, you will in general
have very different standing waves on the two sections. So, for
example, if you connect the output of a transmitter to a 50 ohm line
that goes for some distance, and that connects to a 250 ohm line
that's an even number of quarter waves long, and at the end of that
line there's a 50 ohm load, assuming the 250 ohm line is lossless, the
50 ohm line will see a 50 ohm load and have no standing wave. But the
250 ohm line has a 5:1 SWR.

Similarly, though the antenna conductors may have a large standing
wave on them, they may reflect a load to their input, their feedpoint,
that allows a low SWR on the feedline connected to that feedpoint.

You might think of the antenna as a "lossy transmission line," where
its loss is (mostly) radiation. You can then see another example
using just transmission lines...this time the 50 ohm line from the
transmitter connects to a piece of 75 ohm line. The 75 ohm line is
some even number of half-waves long, and it happens to have 7dB of
loss -- maybe it's fairly small line, or is several wavelengths long.
(In this case, the loss is as heating in the conductors of the line,
not radiation as in the antenna.) At the far end, it's shorted, so

the SWR at the short is clearly infinite. But at the end connected to the 50 ohm line, because of the loss in the 75 ohm line, the 50 ohm line sees a 50 ohm load, and the SWR on the 50 ohm line is 1:1. Note that along the 75 ohm line, the SWR went from infinity at the shorted far end, to 1.5:1 where the line connects to the 50 ohm line.

Cheers,
Tom

Try the "More options", to the right of your name at the top of the
displayed message. There's a "remove" option in there, that doesn't
appear if you're not the author of the message. I assume that will
delete it, though I don't actually have experience doing that, at
least not recently.

Cheers,
Tom

>CAT5 is called UTP. What does the "U" stand for?

UTP is Unmarked Tangled Pair
STP is Stiff and Tangled Pair

However, UTP and STP are the old designations. ISO/IEC 11801 has
changed the designations:

Old New Screening Pair Shield
UTP U/UTP none none
FTP F/UTP foil none
STP U/FTP none foil
S-FTP SF/UTP foil or braid none
S-STP S/FTP braiding foil

Incidentally CAT7 will be where the 4 pairs are individually shielded.

I can rant on gel filled, UV proof, direct burial, riser cable, plenum
cable, vertical tray cable, flat cable, and other CAT5 mutations if
you want.

Hi to all

In EZNEC, when we want to get the near field datas, there is an option to enter the input power. So for a 2 kW PEP power, in order to obtain the V/m or A/m at a certain distance, should we directly enter 2000 W in the input power window, or should we transform it to the effective power 'RMS' value of 2000/sqrt(2) = 1414,2 W, and then enter 1414,2 W instead?

Thanks for your help

You can get a free email account here:

http://gmx.com/

You can then use that email acount to get a free post/read account here:

http://eternal-september.org/RegisterNewsAccount.php

You will be back in business with tbird and an email that people can
spam from here to high heaven, without worry ...

Just in case you are interested ... good luck, either way.

If you don't want want to mess around registering for the news server
or getting a throw away address, you can use the free nntp.aioe.org.
Just plug it into TB or any newsreader and away you go. There are more
restrictions than eternal-september but if you have a life other than
Usenet they won't bother you...

True, the thing with aioe.org is that you don't need to create a
password and no need for a real email addy, even of the throwaway kind ...

This is great in an aid of making the world wide wiretap more difficult
to track/trace you, couple that up with a phony isp number, change the
volume id only hard drive now and then, and use mac makeup to switch the
mac no. on your nic now and then and it becomes even more difficult, use
another identity to make it appear as if you are really someone else and
you start getting a bit of security ...

Really, no one should be using their real isp for usenet anyway!
Everyone should be pretending like it's 1984, which it is!

One thing most people can't appreciate the advantage of is having your
own email server. I helps a lot when you have a low bit rate connection.

I don't need lamp modules, they are less satisfactory.

Which controller do you have?

And maybe we should move this offline.

I am not familiar with EZNEC, but I would say that you must enter 2000W, simply because the RMS concept cannot be applied to power (only "average power" exists, not "RMS power").

RMS can be used for voltage or current, but not power.

So, "2kW PEP" means that the "average power around the instant in which power is maximum" is 2kW.

Probably EZ-NEC returns you the RMS V/m or RMS A/m values around the instant in which V/m or A/m is maximum.

In the ARRL Antenna Handbook it discusses feeding the Lazy H antenna. The handbook states; "Matching stubs are recommended in cases where a non-resonant line is to be used". Is the handbook referring to coax verses ladder line, is it referring to a resonant length of ladder line verses a non resonant length of ladder line, it is referring to ladder line with an antenna tuner at the transmitter verses ladder line without an antenna tuner? In any case I'm not sure what they are specifically referring to. Clarification requested please.

Thank you,

They are probably worried about losses if there is a high SWR on the
coax feedline. I don't see any reason why the Lazy-H can't be fed with
ladder-line and Z0-matched to 50 ohms at the tuner which will cause a
near conjugate match at the antenna feedpoint and throughout the rest
of the system using low-loss feedline.

A possible explanation is the following one.

If you use an appropriate matching stub at the antenna, the antenna impedance can be made equal to the ladder line characteristic impedance. In such (matched) condition, the impedance seen by the transmitter is independent of the ladder line length. You will most likely need a tuner at the transmitter to adapt that impedance to the 50-ohm transmitter impedance.

On the contrary, not using any stub, the antenna impedance will most likely be different from the ladder line characteristic impedance. In such (unmatched) condition the impedance seen by the transmitter varies with the ladder line length. Trimming that length, you may obtain an impedance close enough to 50 ohm, so avoiding the need for a tuner (although a balun will stiil be needed).

Seems like it would be helpful if the handbook gave you an accurate definition of what they mean by "stub" and "resonant" versus "non-resonant" line. To me, a "stub" means a length of transmission line attached to a feed system (perhaps at the antenna feedpoint, but perhaps instead attached to the through-line feeding the antenna at some point away from the antenna feed point), which is open or shorted at the free end. (It's also possible to have a stub that's tuned by putting a [variable] capacitance across the free end--or an inductance.) That is, a "stub" is NOT a piece of transmission line in series with the feed line (which makes it a part of the feed line). If you have a piece of transmission line feeding the antenna whose job it also is to transform an impedance, it _might_ be called "resonant," though I would much prefer the term "series matching section" of line. That's because, in general, the length might not be an integer number of electrical quarter waves. The series section might be used to tune out reactance as well as transform the resistive part of the impedance.

So my suspicion is that they are using "resonant line" to mean a "series matching section," where the series matching section is (probably) an odd number of quarter waves long, to help match between two different resistive impedances. The ideal impedance of that series section would be the square root of the product of the two impedances (resistances) you want to match between.

I use a program called "winSMITH" which I love because it lets me very quickly see what pretty much any arbitrary "ladder" arrangement of line sections (series and stub)--as well as lumped reactances--will do

to transform any arbitrary impedance. The graphical representation gives me insight into what's going on, and how I can adjust things to get the best match. Though I especially like some of the features of this program, there are other Smith chart programs that will give you similar insights. Several of these programs are free. It takes a bit of playing with them to understand what's going on, but I think it's well worth the time because of the deeper understanding you'll get from them. "YMMV" as they say; if graphs don't do anything for you, a Smith chart probably won't either.

Cheers,
Tom

1461. AIM4170 Presentation -- open-wire feeder TDR scan

Newsgroup: rec.radio.amateur.antenna
Date: 2011-06-12 07:01:39 UTC
From: Ian Wade G3NRW <g3nrw@yahoo.co.uk>
Message-ID: <oGILP+ETRG9NFwjl@ntlworld.com>
Source record: 4512
Cross-posted to: rec.radio.amateur.antenna,uk.radio.amateur

I have added a further update to the AIM4170 Presentation, showing a TDR scan on an open-wire feeder.

Go to: http://homepage.ntlworld.com/wadei/aim4170.htm

then click on the link "AIM4170 PowerPoint Presentation".

New slides 72, 73 and 74 show clearly that although Zo = the calculated free space value at the antenna feedpoint, it is otherwise considerably affected by the feeder’s proximity to ground and other objects.

Zo actually falls as the feeder descends from the shack window to the garage, remains more-or-less constant as it passes over the garage roof, and only begins to increase again as it traverses the hedge and passes through the tree. Note also that the impedance decreases slightly where the feeder narrows at the antenna feedpoint.

Yet another example of the incredible versatility of the AIM4170.

K8JS was correct about the factory balun in the Dentron MT-3000a not working correctly on 10 meters (see below). I by-passed the built in balun by using a 3 foot jumper out one of the other antenna coax jacks and then connecting the 450 ohm ladder line to the external 1:1 balun. The Lazy H antenna lit up! Now it is performing like I was expecting, and the missing gain is definitely there. I initially tried an external 4:1 balun, but since I had previously trimmed the 450 ohm ladder line to get a better match to the tuner I wound up getting a better match with an external 1:1 balun. Now I need need to replace the internal 4:1 balun in the Dentron MT-3000a, so I can get my open wire antenna position back.

I have to retract my previous statement when I said the Lazy H antenna sucks. They rock. It is the built in factory 4:1 balun in the Dentron MT-3000a that sucks on 10 meters. With the new balun the Lazy H antenna is performing beautifully. I already built a second Lazy H, and I have it pointing in a different direction. The side rejection on those antennas is pretty impressive, and both Lazy H antennas are now blowing away the rotatable dipole in their favored direction.

Thank for all the help,

Michael Rawls

Hi Michael,

That sounds good.

>It is the built in factory 4:1 balun in the
>Dentron MT-3000a that sucks on 10 meters.

It probably sucks equally on all bands.

>With the new balun the Lazy
>H antenna is performing beautifully.

It would serve us all, and specifically you, if you would describe
EXACTLY what the difference is between the factory built BalUn and
your own new BalUn.

First, can you distinguish between Voltage BalUns and Current BalUns?
They go by other names such as Ruthroff and Guanella. Can you
enumerate the characteristics beyond the transformation ratio?

Do you understand the concept of Common Mode current, and how (not how
much) it impacts performance?

1464. Reflection coefficient for total re-reflection

Newsgroup: rec.radio.amateur.antenna
Date: 2011-06-12 19:05:50 UTC
From: walt <walt@w2du.com>
Message-ID: <9a2f86b0-e043-422c-bb29-666f57cc2dbd@w10g2000yqh.googlegroups.com>
Source record: 4515

I have a question for W5DXP, KB7QHC, W7ITM and K0TAR relating to transmission lines.This is not a trick question. This is a straight-forward question for which I 'm dead serious. The answer will involve a resulting reflection coefficient.

Assume a 50-ohm line terminated in a purely resistive 150-ohm load, yielding a 3:1 mismatch with a voltage reflection coefficient Vρ equal to 0.5 at 0°. We want to place a stub on the line at the position relating to the unit-resistance circle on the Smith Chart. For a 3:1 mismatch this position is exactly 30° rearward from the load, and has a voltage reflection coefficient Vρ equal to 0.5 at -60°. The normalized line resistance at this point is 1.1547 chart ohms, or 57.735 ohms on the 50-ohm line, for a line impedance of 50 - j57.735 ohms.

Placing a short-circuited stub having an inductive reactance of +j57.735 ohms on the line cancels the line reactance, establishing a new line impedance at this matching point of 50 + j0. However, a lot more is involved than just canceling the reactances to establish the impedance match. To begin, the stub generates a new, secondary, canceling reflection that cancels the primary reflected wave generated by the mismatched line termination.

Recall the voltage reflection coefficient Vρ of the line impedance prior to placing the stub--Vρ = 0.5 at -60°. The corresponding current reflection coefficient Iρ = 0.5 at +120°

We now look at the voltage reflection coefficient of the stub, which is Vρ = 0.5 at +60°, and the corresponding current reflection coefficient of the stub which is Iρ = 0.5 at -120°.

Observe that resultant angle of the voltage coefficients is 0° and resultant angle of the current coefficients is 180°, all with the same magnitude--0.5. It is well known that when these respective coefficients exist at this point, the matching point, this condition establishes a virtual open circuit to rearward traveling waves at this point, prohibiting any further rearward travel of the reflected waves, thus reversing their direction toward the load.

Consequently, the result is total re-reflection of the two sets of reflected waves at the match point.

Now the question--what is the resultant voltage coefficient of reflection at the match point? My position is that ρ = 1.0, which indicates total reflection. However, I've been criticized on this value, my critics saying that because this virtual open circuit was

established by wave interference, ρ cannot equal 1.0. They assert
that ρ = 1.0 can be obtained only through a physical open circuit.

So I now ask you, am I correct in saying that the reflection
coefficient in this situation is 1.0? I'm holding my breath for your
answers.

Walt

Unfortunately, the symbol for rho came thru as 'n' with a diacritical
mark over it. That incorrect character should be replace with the
Greek symbol rho, which this venue cannot print.

Walt, some of us have previously discussed the difference between a one-port s11 (reflection coefficient) and a two-port s11 and I think that difference is what you are seeing. The one-port s11 (rho) is a virtual reflection coefficient based on the available system information. In that case, rho is 1.0. However, if we use the two-port parameters, I believe s11 (rho) will be 0.5. The matching stub complicates the analysis so maybe we can reduce the complexity using a slightly different example about which you can ask the same question and the answer will be a little easier.

--50 ohm--+--1/2WL 150 ohm--50 ohm load

It's essentially the same problem without the complexity of the stub. There is a 50 ohm Z0-match at point '+'. The one-port s11 (rho) looking into the Z0-match point from the source side is 0.0 because there are no reflections. The one-port analysis is blind to any interference that might be recognized if we were using the two-port analysis.

The one-port s11 (rho) looking back into the Z0-match from the load is 1.0, same as your virtual open/short. The one-port analysis used for your virtual open/short concept is unaware of the interference that is visible in a two-port analysis. A one-port analysis cannot tell the difference between an actual reflection and a redistribution of energy associated with superposition interference.

However, the two-port s11 (rho) looking into the Z0-match from the source side is 0.5, i.e. (150-50)/(150+50). Interference is not invisible in the two-port analysis. In fact, when the voltage reflected toward the source is zero, there is total destructive interference in the direction of the source.

b1 = s11*a1 + s12*a2 = 0

where all math is phasor math. The two terms cancel destructively to zero. The ExH energy components in those two terms are redistributed back toward the load.

In a two-port analysis, the reflection coefficient looking back into the Z0-match from the load is called s22. The matching equation is:

b2 = s21*a1 + s22*a2

All of the destructive interference energy involved toward the source is redistributed back toward the load as constructive interference. But such is invisible in a one-port analysis such as your virtual open/short circuit.

There is nothing wrong with your one-port virtual open/short circuit analysis. There is also nothing wrong with the more in-depth two-port analysis. It is simply that more information is available during the two-port analysis.

Over on another newsgroup, some reported using a one-port analysis almost all of the time. Tell your critics that you are using a one-port analysis where the interference information is simply not available during the analysis.

What is the one-port reflection coefficient looking into a Z0-match from the source side? 0.0
What is the one-port reflection coefficient looking into a Z0-match from the load side? plus or minus 1.0

That is what you are doing with your virtual open/short and there's nothing wrong with a one-port analysis.

Hi Cecil and Richard,

Thank you for the insightful response, Cecil. However, when you go to the 2-port version I’m unable to correlate that configuration with my stubbing problem.

Here’s what my problem really involves. Referring to Eq 8 in the first part of Steve Best’s three-part article published in QEX, the equation is as follows: The section within the parentheses is the voltage-increase factor when all reflections have been re-reflected. That section is 1/1 - (rho_’a’ x rho_’s’), where ‘a’ is the mismatch at the antenna (the load) and ‘s’ is the mismatch at the source.

We’re considering the source to be an RF power amp, where we know the output source resistance is non-dissipative, thus re-reflects all reflected power incident on it. I maintain that the reflection coefficient at the source is 1.0 because of the total re-reflection there.

Now consider working with the output of the pi-network of the RF anp, where I believe the reflection coefficient is 1.0, and the 3:1 antenna

mismatch that yields a reflection coefficient of 0.5. Plugging these coefficients into the equation section yields 1/1- (1 x 0.5), which equals 2.0, which is incorrect, making that equation invalid, IMHO. The correct value with these coefficients should be 1.1547, not 2.0.

However, mathematical experts say that the equation is correct, saying that rho_¬'s' cannot be equal to 1.0, because the virtual open circuit was established by wave interference, not a physical open circuit.

The reason that I didn't say anything about the stub example is
because I cannot comprehend it without a schematic. That's why I
changed examples. Do you agree with what I said about my example?
Could you post a schematic of your first example? It is the "series
stub" part that I don't understand. Such is usually called a "series
section" because a stub is usually a parallel dead end open or short
circuit. It is also difficult to comprehend how a two-port analysis
could be done at the stub connection point. Wouldn't that require a
three-port analysis?

> We're considering the source to be an RF power amp, where we know the

How's about we limit the *initial* discussion and examples to a source
with zero incident reflected power so the source impedance doesn't
matter? IMO, a two-port analysis of a Z0-match point will reveal the
main ingredients of the energy flow.

> However, mathematical experts say that the equation is correct, saying
> that rho_¬'s' cannot be equal to 1.0, because the virtual open circuit

A one-port analysis cannot tell the difference between wave
interference and reflections. You are correct that the reflection
coefficients are not necessarily the same between a one-port analysis
and a two-port analysis. Your "mathematical experts" don't seem to
understand the limitations of a one-port analysis. It's akin to not
knowing what is inside a black box, i.e. one cannot tell the
difference between a resistor and a virtual resistance. However, with
a two-port analysis, one can tell the difference. It appears that your
"mathematical experts" are insisting on a two-port analysis such as
provided by the s-parameter equations:

b1 = s11*a1 + s12*a2

b2 = s21*a1 + s22*a2

Cecil, the series stubbing appears in Reflections, Chapter 23, with the same values as I presented above, with detailed diagrams shown in each step in the progression of the explanation. I hope these diagrams can help.

As I said in the previous post, the experts were referring to the output of the RF amp as not establishing a reflection coefficient rho = 1.0, which has put me in a corner.

Sorry Cecil, I can't correlate a two-port configuration using S parameters with the problem I have. Thanks a million for the discourse.

Walt

The corner I'm in, Richard, is that In Reflections 3, Chapter 25, I assert that Steve Best's Eq 8 in the first part of his three-part article appearing in QEX is invalid, because it gives incorrect answers when I plug in what I believe are correct values of reflection coefficients. Yet his equation agrees with that of Johnson on Page 100 of his "Transmission Lines" text book. In addition, a mathematics expert whom I respect says Best's equation is correct. So I've got to make the decision whether to delete my criticism of his equation or leave it in and be accused of criticizing him incorrectly. What to do!

Hi Walt,

So this is not only double-deep, through your work to Steve's, but
triple deep then through Steve to Johnson.

Lacking the necessary, culminating edition of Johnson's, I still don't know what the corner is.

Lacking the complete math from all sides of the argument (not somewhere I would like to go), and noting that many authors (not making attributions here) frequently ignore some relatively basic mandates where they don't matter, to then expand into situations where they do matter; then I don't really trust heavily editorialized math analysis.

I note your summary statement for Steve that you find contentious, viz.
"A total re-reflection of power at the match
point is not necessary for the impedance
match to occur."
is one where I would agree with Steve; but not necessarily for reasons brought forward. What is worse, this simple statement may mean three things to two people.

I'm surprised that there were no FUs to this (at least in ukra).

This looks like a seriously useful bit of kit for the antenna
experimenter, but whether I could personally justify one for my
string-and-sealing-wax approach to short wire antennas is
questionable.

Although this device means one could fine-tune one's antenna, the one
thing that affects very nearly every Amateur is the ground around
their installation, probably up to 10 lambda before the various fields
and rays begin to sort themselves out. There seems to be no equivalent
piece of kit that would enable such an assessment to be made or its
effect on the station's performance to be estimated. I guess most of
us take the view that one lives with what one has, and can't do much
about it anyway.

I had a quick look at this piece of equipment, but couldn't see it
offering anything more than the MRS MiniVNA, which is a two
port device and a more versatile instrument.

(A one port device is useless for setting up filters etc.)

Yes, it's about that. My bit of Bedfordshire is so dry at present that
I reckon the ground conductivity will be so low that I'm going to have
to put down a ground mat/radials rather than try to get ground spikes
down into the damp sub-soil.

I don't think RS232 is going to die just yet.

It's still easy to cater for, but as you say, USB
is a lot more convenient since just sbout every PC
these days has them.

However I'm always cautious about anything software
driven becoming obsolete.

Hence I also keep a Palstar ZM30 around for HF work,
that doesn't require a PC, but still gives me all the relevent
data for antenna work.

And after all that, I still insist on a final tune up with a
field strength meter ;-)

The mini VNA being a two port device is great for making high/low
/bandpass./notch filters and instant seeing the response.

You can line up IF xtal filters etc. Very versatile.

Thoughts on voltage vs power, reflection vs interference:

What most RF people do is deal exclusively with voltages. Power is considered only at the beginning and end of a voltage analysis, NOT during the voltage analysis. If joules/second are to be tracked seamlessly throughout the analysis, a working knowledge of the effects of superposition/interference is absolutely necessary. Optical physicists do not have the luxury of working exclusively with voltages, as we do in RF, so they must necessarily understand superposition/interference and be able to track every component of irradiance (power density).

I took a look at Johnson and he is dealing with voltage, not power, and certainly not with dissipationless resistances as part of the generator source impedance. He uses 'k' sub-script 'g' as the symbol for the voltage reflection coefficient. I'm going to use 'rho' for his 'k' with braces {g} indicating subscripts. His *voltage* reflection coefficient at the generator is:

rho{g} = (Zg-Z0)/(Zg+Z0)

which is just standard *voltage* wave reflection mechanics. What happens to the energy (power) in superposed waves is completely transparent when superposing voltages. For instance, let's say we have two 200 watt waves in a 50 ohm environment which makes each of their voltage magnitudes equal to 100 volts RMS. The electric fields of the two waves are 120 degrees apart. What happens when we superpose 100 volts at +60 degrees with 100 volts at -60 degrees?

Every student of three-phase power systems knows the result will be 100 volts at zero degrees. All is well until we take a look at the energy in those two superposed waves. Each wave is associated with an ExH amount of power, V^2/Z0=200w, for a total of 400 watts in the two waves. The resultant (total?) superposed wave contains 200 watts of ExH power. Most people don't give this idea a second thought but where did the other 200 watts go? To answer the question, one must understand destructive/constructive interference. In the above example, there is 200 watts of destructive interference present so the resulting "total" voltage is not the only component of superposition.

If the above occurs in a transmission line, the amount of destructive interference energy that is lost in the direction of superposition, e.g. toward the load, is redistributed in the only other direction possible, i.e. toward the source. There is a second 200w wave generated that travels toward the source but that fact is not covered when voltage superposition is involved. Note that it is a reverse-

traveling wave but it is technically not a reflection of a single wave as it is the result of superposition of two waves.

Voltage superposition takes care of itself and everyone believes in the conservation of energy principle which is probably why very few people ask, "Where does the power go?" It is only when we are trying to track energy throughout the system that we are forced to understand the effects associated with interference.

Thoughts on one-port analysis vs two-port analysis.

Sources are necessarily treated as single-port devices. We know we often get completely different reflection coefficients when treating something as a single-port device vs as a dual-port device. For instance, most of us treat a dipole feedpoint as a single-port device when it is actually far from being a single-port device. In reality, many other things besides a single reflection, are happening at a dipole's feedpoint. The actual physical reflection coefficient at the feedpoint of a "50 ohm" dipole fed with 50 ohm coax is around 0.845 because the characteristic impedance of a #14 wire 30 feet above ground is around 600 ohms. Proof: Eliminate the reflections from the ends of the dipole by terminating the ends of the inv-V dipole to ground through 600 ohm resistors and the SWR on the 50 ohm feedline goes to 12:1.

Because of reflections from the ends of the dipole, a lot of interference is happening at the feedpoint which results in a *virtual* reflection coefficient of 0.0 only because of the single-port analysis that is ordinarily used. IMO, a virtual reflection coefficient is a *result* and cannot cause anything including reflections. IMO, only physical reflection coefficients, i.e. physical impedance discontinuities, can *cause* reflections. Much of what we consider to be reflections are the result of interference.

Seems that something similar, but more complicated, is happening inside a source where there is an active-source component in the mix. IMO, what is happening to the energy inside a source cannot possibly be understood without taking the effects associated with interference into account.

Walt,

I've gotten confused here...I see in your follow-up posting that the "stub" is to be in series with the line, but you also talk about a shorted stub. It doesn't make any sense to me to put a shorted section of line in series with another line, so my confusion starts. Next, I'm assuming that we're talking about lines with real (non-reactive) impedance, so I'm wondering why you go 30 degrees from the load to a point where the reflected impedance is, as you say, 50-j57 ohms. I'm assuming we want to get to 50 ohms, eventually, and the series section to do that from this 50-j57 ohm point would have to have infinite characteristic impedance. Why not just start from the load and use a line whose impedance is sqrt(150*50) and is 1/4 wave long? That seems a no-brainer.

Or, if you want to use 50 ohm lines, go 60 degrees from the 150 ohm load and tap into the line with a shorted _stub_ (not series line section) that's about 40 degrees long, and you have your match to 50 ohms.

But of course, you're not necessarily looking for a straightforward solution to a matching problem here, you have a question about reflection coefficients. Since I got confused about just what the configuration really is, I didn't even try to sort out the rest of the posting about reflection coefficients, and I'm afraid I thus can't offer an answer to your ultimate question. I will say, though, that in a (theoretical, since lossless is assumed) system of TEM lines having real (non-reactive) impedances and loads that don't generate power, you can have any reflection coefficient magnitude from zero to unity. If you have dissipative loads, the only way you can get to unity reflection coefficient magnitude is to arrange the lines to prevent any power actually being dissipated in any of the loads: e.g., shunt the loads with shorts, or put opens in series with them.

Cheers,
Tom

Tom, I didn't know initially that the example was in "Reflections III". A series stub can be used instead of a loading coil on a wire antenna. I had never seen a series stub used in such a manner on a transmission line and that's why I was confused. I'm assuming that the center conductor is broken and one side is connected to the inner conductor and one side is connected to the braid on a stub, but I am not sure that is correct. There's got to be a less complicated example that we can use.

Thanks John, I can't help but point out that such a "series stub"
unbalances the transmission line currents resulting in common-mode
currents on the outside braid and is probably a deviation from the
original design specifications. There has got to be a simpler example
that illustrates the question/answer. I thought I had it with my Z0-
match example but maybe not.

Thanks John, but I would like to see the schematic for coax. Shirley,
one doesn't cut the braid and add a stub?

Thank you for the response, Tom, but apparently you're not familiar with series stub vs parallel. You are correct that going 60° from the load is the location for a parallel stub to obtain a line impedance of 50+j0 ohms from the stub to the source. That location is the second time you pass the unity-resistance circle on the Smith Chart, only this second time it's the unity-conductance circle. Either method of stubbing works. The first time the unity-resistance circle is reached with a mismatch of 3:1 at the load is 30°, where the reflection coefficient rho = 0.5 @ -60°. The normalized line impedance at that location is 1 - j1.1547 chart ohms, or 50 - j57.7 ohms relative to Zo = 50 ohms. A shorted stub in series with the line at that location of length that will derive a normalized inductive reactance of +j1.1547 generates a secondary reflection that cancels the load-generated reflection. The voltage reflection coefficient of the stub is 0.5 @ +60°, the opposite of the voltage coefficient of the line at that location. In addition, the current reflection coefficient of the line at that location is 0.5 @ +120°, while the current reflection coefficient of the stub is 0.5 @-120°.

Consequently, the resultant voltage coefficient is 0.5 @ 0° and resultant current coefficient is 0.5 @180°. When these specific coefficients occur at the same location, a one-way virtual open circuit is established that prevents any further rearward travel of the reflected waves, but reverses their direction to forward, and in phase with their respective voltages and currents delivered by the source.

The problem I'm having is where the canceling reflected wave is established either by the antenna tuner, or the optimum tuning and loading of the pi-network tank circuit of the RF amp. We know that the canceling wave in the tuner occurs at its input terminals. However, many are uncomfortable in thinking of the output source resistance of the pi-network tank circuit as being non-dissipative (which it is), and thus re-reflects all reflected power incident upon it, and therefore, IMHO, the reflection coefficient of both the antenna tuner and the tank circuit is rho = 1.0.

My problem is in using Eq 8 that appears in Part one of Steve Best's three-part article in QEX on wave mechanics. The simplified version of Eq 8 is: 1/1-(rho_s x rho_a), where 's' = source resistance of the tank, and 'a' = mismatch at the antenna-feed line junction.

Mathematicians say Eq 8 is ok, and it does agree with Johnson on Page 100 of his text Transmission Lines. However, when I plug in 's' = 1.0 for the total re-reflection at the tank, and 'a' = 0.5 for the reflection at the antenna-feed line junction, Eq 8 delivers a value of 2, which is incorrect--the correct value is 1.1574, the voltage-increase factor when all reflected power is re-reflected with a 3:1 mismatch.

In Reflections 3, Chapter 25 I stated that Best's Eq 8 is incorrect, based on my calculations. However, mathematicians whom I respect say I'm wrong. Evidently, I'm going to have to delete that portion of

Chapter 25 to avoid having readers view incorrect information. What's going on here?

Tom, if you have the time and the inclination to review this post, I'd be grateful for your opinion on whether the non-dissipative tank circuit can have a reflection coefficient of 1.0.

In a one-port analysis, virtual impedances cause reflections. In a two-port analysis, only physical impedance discontinuities cause reflections. As I see it, that is the entire problem in a nutshell. You are using a one-port analysis for virtually :-) all of your analyses, including your source analysis. Your detractors are trying to talk you into using a two-port analysis.

Cecil, as I said earlier, I can't see any relation between a two-port configuration and the tank circuit of an RF power amp. Why are you pushing it? Can't you just tell me whether you agree that the reflection coefficient at the output of the tank circuit is rho = 1.0 or not. If you don't believe it does, even though it re-reflects all the reflected power incident on it, then please explain what you believe the reflection coefficient is at this point.

Walt, W2DU

Ah, OK. Now I understand what Walt meant... Though it's possible to use a series stub on a transmission line, as you say, it's not all that common in practice. I suppose that's why my mind wasn't going there. Mea culpa. Perhaps now I can go back and look at Walt's original question and make more sense out of it.

When a series stub is used in an antenna (as in a quarter-wave stub coupling colinear half-waves), King points out that coupling from the antenna fields to the wires in the stub, when the stub is an open-wire line perpendicular to the axis of the half-waves, is an important factor in how the stub operates to establish in-phase currents on the adjacent half-waves... I see you made a comment about antenna currents on the stub in John Smith's example, too.

Cheers,
Tom

OK, now that I understand the series stub configuration, I have to ask: "the" reflection coefficient looking into WHAT? Looking back toward the source in its feedline? Looking back toward the source but including the series stub? Looking toward the load, including the series stub?

The way I look at this problem is as a measurements person: once I know where I'm looking, how will I measure the value of the reflection coefficient? The way I would normally do it is with a network analyzer. If I want to do it in the presence of significant power coming from a source, I can set up directional couplers to allow me to introduce a test signal (that I must be able to distinguish from the power coming from the source) and observe the reflection.

You can also replace each piece of transmission line (including the piece that's the stub) with an S-parameter two-port, and the source and load as S-parameter one-ports, and apply standard S-parameter math to see what the reflection coefficient is looking into any particular port.

I suppose this is going to give you an answer different from the one you're hoping for...but I believe it's consistent with the definitions for linear system analysis that I've always used.

Consider the case of two identical sources generating the same signal but 180 degrees out of phase. Each source is connected to a length of transmission line, and the two lines are identical. Just for fun, the line impedance equals the source impedance. The free ends of the lines are connected in parallel and to a resistive load. Of course, we find that the signals cancel and there is no power dissipated in the load. Would we say that the reflection coefficient magnitude looking back into either line toward the source is unity? I would not! I would say it is zero, since any signal I send in that direction is absorbed in the source. Note in this example that you can disconnect the load and not change anything. Then you simply have the signal from each source traveling to the other source and being absorbed; if you put the sources on two different frequencies, you'll see no standing wave for either frequency (though you'll have to

average for a while to be sure about that, if the frequencies are close together). And note, please, that "absorbed" is not in general the same thing as "dissipated."

Cheers,
Tom

Personally, I didn't find anything wrong with parts 1 and 2. It's in
part 3 where Dr. Best gets lost. In an exchange on this newsgroup
before the article was published, he asserted that there was no
interference occurring at an impedance discontinuity on a transmission
line. When he published his component powers, he took into account
P1and P2 while completely ignoring (what I have dubbed) the component
powers, P3 and P4 in the opposite direction. He even invented
something like two phantom waves traveling forever in the direction of
total destructive interference while transporting energy but
completely canceling each other in the process, obviously a physical
impossibility.

Tom and Cecil,

My use of the series stub wasn't meant to be of practical use. I used
it only as a tool to explain a simple matching procedure. I used
series rather than parallel, because I wanted it to be simple to use
for those who are not as accustomed to admittance procedure as they
are with impedance. Sorry if I misled you.

I'm sorry to have misled you in bringing up the series stub problem.
What I'm really concerned about is the reflection coefficient at the
output of the tank circuit of the RF power amp. Being non-dissipative
it cannot absorb the reflected power, so it must re-reflect it.
Therefore, my position is that its reflection coefficient rho = 1.0,
My critics say that a rho = 1.0 cannot be established when the virtual
short is caused by wave interference. However, if Best's Eq 8 is
valid, then why does it yield an incorrect answer when I plug in rho s
= 1, and rho a = 0.5, which gives 2 as the answer, instead of the
correct 1.1547 as the correct answer.

Now that I've narrowed the problem down, what do you believe is the answer? Your answer will determine whether I need to delete the pertinent paragraph from Chapter 25 in Reflections 3, in which I have declared Best's Eq 8 invalid.

It includes a point argued by many, and which you make a condition of
success for your argument:
>Being non-dissipative
>it cannot absorb the reflected power, so it must re-reflect it.

Your argument now applied at two points, one not illustrated in your
references (the source):
>Therefore, my position is that its reflection coefficient rho = 1.0,

The counter argument:
>My critics say that a rho = 1.0 cannot be established when the virtual
>short is caused by wave interference.
which they express NOT as a condition of the tank circuit, but of the
matching hardware.

>However, if Best's Eq 8 is
>valid,

You have acknowledge that experts in math whom you trust say it is
valid. This yields a paradox. By all the shifts in focus, it is
apparent that:
1. You are both right;
2. You are both wrong.
3. One of you is right, and one of you is wrong;
more likely given the drift of focus:
4. You are at cross purposes and arguing two different things.

>Now that I've narrowed the problem down, what do you believe is the
>answer?

You have not narrowed the problem down at all. It is composed of a
succession of premises that all have arguments for-and-against them.
This compounds the uncertainty. It also brings the hazard of any
single premise being rejected bringing down the entire goal you are
pursuing.

* * * * * * * * * * * * * * * * * * *

To put this bluntly, let's test the assertion repeated here:
>output of the tank circuit of the RF power amp.
>Being non-dissipative
>it cannot absorb the reflected power, so it must re-reflect it.

Odds are, you will lose support from at least half of the readership for this statement alone - and it isn't even in your written work that I've provided links for, and it certainly doesn't appear in Johnson. It is not discussed by the experts in math either. It is a flyer, a leap of faith whose validity is now emeshed with the outcome of another problematic discussion.

Steve's opinion:
>viz.
> "A total re-reflection of power at the match
> point is not necessary for the impedance
> match to occur."
offers NOTHING to the matter of non-dissipation.

Odds are, Steve could easily lose support from at least half of the readership for this statement alone. Unfortunately, that doesn't leverage your position one iota.

There are too many irons in the fire.

Thank you for your insightful response, Richard. However, I must plod on, and introduce the results of my own measurements, the data of which appear in Chapter 19, Sec 19.14 of Reflections 3. Using a Kenwood TS-830S I measured the parameters required to prove the output source resistance of the tank circuit of its RF power amp is non-dissipative. The measurements also prove that the reflected power incident on its output is totally re-reflected. From reading an earlier post of yours, Richard, I know you have read this portion of Chapter 19, and you agreed with it. My measured data conflicts with Best's Eq 8, so there's got to be a valid answer to this dilemma, but where?

Hi Walt,

Yes, I am very familiar with your bench work. I am very annoyed by those who trivialize it. I am further annoyed by those who patronize you to then shift the parameters to explain something else - completely abandoning you.

However, I also acknowledge that I can hurt your feelings about where I stand on these matters. Yes, to a limited degree, I do agree with much of your assessment, but I do not follow it into the arena of where you express it as being "non-dissipative."

However, my denying this proposition does NOT mean I dispute your other proposition of complete reflection. This cross connection of several topics is where things get overly complex and gives the entire discussion the appearance of a house of cards.

I cannot tell what your agenda is, but the material you quote as source, and for which I have provided links to in this thread - all seem a subtext to non-dissipative sources. Attention directed towards this pursuit of matching points rendered in stubs seems like tea leaf reading to resolve a larger issue.

As a student, tech, and engineer employing a LOT of precision waveguide technology, I am quite comfortable with the components and topologies you describe. Arguments for wave interferences being rendered into useful circuit constructs (that is, constructed on the basis of wave interference) has been with us easily since the early 40s. One component, the ATR tube, is one I have handled and replaced to insure the proper operation of RF paths being steered in

waveguides. One proviso, however => for any of these "virtualizations" to work, they require a physical (and dissipative) element as the initiator. Waves do not interfere without the presence of a physical element (often some form of detector, or minimally a load).

Thanks again Richard, for your insightful response. And goodness no, Richard, you won't hurt my feelings. I like being correct, but if I'm not I surely want to be told about it. This situation is no different.

However, if you're not following me on the 'non-dissipative' path, I'd like you to review the last portion of the TS-830S experiment, and follow the numbers. If you don't have that material in front of you, you can find it again on my web page at www.w2du.com. Click on 'Preview Chapters from Reflections 3', and then click on Chapter 19A, which is a part of Chapter 19 in the 3rd edition.

Observe that when the load impedance is changed from 50+j0 to the complex impedance 17.98 + j8.77 ohms, the plate current rose expectedly from 260ma to 290ma. This change occurred because the amp is now mismatched, and the pi-network is also detuned from resonance. The unwashed would conclude that the reflected power caused the increase in plate current. However, one will also observe that after the pi-network has been retuned and adjusted to again deliver all the available power into the otherwise 'mismatched' load (which is now matched to the source), the plate current went back to it's original value, 260ma. In addition, the amp returned to deliver 100w into the complex impedance at the line input, with the 30.6w of reflected power in the line, and adding to the 100w of source power, making 130.6w incident on the mismatched load, absorbing 100w and reflecting 30.6w.

IMHO, these data prove beyond doubt that the pi-network not only didn't absorb any of the reflected power, but totally re-reflected it. In my book this says the pi-network reflection coefficient rho = 1.0. How can anyone disagree with this?

Hi Walt,

There is absolutely NOTHING that I can dispute in your numbers or
method. However, as to "dissipation" this says nothing.

As for what it says about the reflection coefficient, I would agree
with you. However, the math and the math experts you speak of - they
are not answering the model we are examining above. You distracted
them with stubs and reflecting waves.

If you cast this agreement in the reflection coefficient back into
effects purported to exist in the matching with stubs model, we may
yet argue.

*** Nothing further useful about the topic is to be found below ***

There is a curious side bar to this found at:
http://www.w5big.com/purchase4170c.htm
Observe the second data screen that purports to examine a mismatch through a length of both RG58 and RG59 terminated with 100 Ohms.

Of particular note is the distinct transition from the Zc of 50 Ohms to the Zc of 75 Ohms and the similarly distinct transition from the Zc of 75 Ohms to the termination R of 100 Ohms. Note that the transitions both span a distance of 2 feet. 2 feet is not insubstantial compared to connection technology that spans, probably, no more than one tenth that distance. Whence the extra 11 inches on both sides of the connection plane of either connection?

In the physics I've been studying for the past 10 years, near fields, this would not be unusual. In fact it would be expected. There is a transition zone (in waveguide design, there would be a taper or a sweep section to anticipate this and they would be physically large in terms of wavelength) not a transition cliff.

Similarly, at the connector to your TS-830S, there is a zone that surrounds it that only approximates the 50 Ohm which occurs (in the terms of this link's demonstration) some distance away, deep inside your TS-830S.

To me, dissipation inhabits this zone (certainly large enough for the tube and tank to occupy) and embraces the match with a complex addition of phases that could result in loss or even gain. This is also to say that I do not subscribe to dissipation being all about loss - especially when the hand of man is on the tuning knob instead of letting the chips fall where they may.

Walt, I can only get your 1.0 - j1.1547 normalized impedance value (looking into the line towards the normalized load of 3.0) if I move 60 degrees, not 30, from the load towards the generator. I'm also assuming a lossless line. Sincerely, and 73s from N4GGO,

Hello JB, thank you for the response. I'm sure I understand what's
going on. When you view the Smith Chart at the unity resistance circle
with a 3:1 mismatch the normalized impedance there is 1.0 - j1.1547,
as you stated. However, a radius through that point yields a voltage
reflection coefficient rho = 0.5 @ -60°. In other words, the radial
line intersects the periphery of the Smith Chart at -60°.

As I'm sure you know, reflection degrees equals two electrical
degrees. Therefore, the normalized impedance 1.0 -j1.1547 ohms occurs
at 30° rearward of the load. That OK?

In the absence of a Smith Chart here's an easy way to determine the
reactance appearing at the unity resistance circle for any given
degree of mismatch:

1/(sqrt SWR/
SWR-1)

Fixing the equation: 1/(sqrt SWR/SWR-1)

Well, I'm not clear what you mean by "rearward of the load". At 60 degrees toward the generator the normalized impedance looking into the line is 1.0 - j1.1547 ohms and that corresponds to a reflection coefficient of -j1.1547/(2-j1.1547) or alternatively, 0.5 @ -60 degrees (sorry my char set doesn't do Steinmetz notation). So I think we're in agreement here. What more needs to be said? Now put in a shorted stub (of appropriate length at the desired frequency) in series to tune out (cancel) the reactive part of the line impedance. The combination of the series stub and the line will appear as 1.0 + j0 to the generator/source and the reflection coefficient is now 0. How could it be anything else (at the desired frequency) in this scenario? You don't need a discussion of travelling waves to arrive at the correct answer. The reflection coefficient corresponding to a normalized (say to 50 ohms) impedance zx = Zx/50 is rho = (zx - 1)/(zx +1). Clearly a values of rho = 1 + j0 or -1 + j0 correspond to a zx values of infinity (open circuit) or zero (short circuit), respectively.

You might want to think of the shorted line stub as inside one box and the transmission line + 150 ohm load in another black box. Let's assume someone hands you these two boxes and you have no idea what's inside but you do have access to set of terminals (input port) on each box from which you can measure steady-state impedance of each. At some frequency you find the normalized input impedance on one box is +j1.1547 ohms and on the other box at that same frequency it is 1.0 - j1.1547 ohms. Now you connect the boxes is series and measure the impedance of the series combination again at that frequency. The point I'm making here is that at the terminals of either of the boxes you measured the impedance at some frequency - it doesn't matter what's inside the box. (Of course the impedance behavior over a range of frequencies certainly is dependent on the circuit topology within the box.) Sincerely,

Thanks again for the response, JB. What I mean by rearward of the load
is simply going toward the source from the load. But are we in
agreement? We probably are as long as we agree on terminology

regarding the Smith Chart. The unity resistance circle for a 3:1 mismatch yields a normalized impedance of 1 - j1.1547 as you know. As I said in my previous post, a radial line passing through this point on the unity-resistance circle joins the periphery of the Chart at -60°. It important to note that this -60° is reflection degrees, which is two-times greater than degrees along the transmission line. Therefore, the normalized line impedance of 1 -j1.1547 appears at 30° from the load toward the source on the xmsn line, not at -60°. Hope we're in agreement on this.

I found an adapter in my junk box that goes from a BNC to something similar to a male N type. It will not mate up to a female N connector.

A normal N male connector has the center that is just about even with the shell that screws onto the female end. This connector has the male part sticking out about 1/4 of an inch past the shell. It will fit the female N connector except when I go to screw them together, there is not enough threads to mate and make a good mechanical connection.

Anyone know what type of connector this is ?

Two suggestions come to mind. First, have you tried Pasternack's
connector identifier PDF (www.pasternack.com/pdf/catalog/
ConnectorIdentifier.pdf) or equivalent? Second, could it be a damaged
BNC-to-N? It seems strange to have the pin sticking out that far; it
would be inviting damage to the pin.

Cheers,
Tom

I have not seen that url. I did not see one like it there.

It could be dammaged. It is not just the center pin that is sticking out
past the threaded shell, but the whole inside part of what would be a normal
N connector. It will pass power, just the threads will not screw together.

1514. Antenna advice/suggestions needed...

Hiya...
Newly minted “non technical” ham here :-)

Been a SW DX’er for many years and decided to get my ham ticket recently.

Now that I've decided on what to get for my first ham radio, (TS-590s) I'm moving on to deciding on an antenna. The goal will be DX'ing the ham bands with phone and eventually CW. I'm looking for an antenna set up that will work on 10 to 80 meters. Of course, multiple specific antennas would be an ideal, but that is not in the cards. I've had a few options in mind. All of course, would be coupled with an antenna tuner if the internal auto tuner on the radio cold not do the job.

1. Set up a butternut HF9V on a roof mount approx 30-35 feet above the ground with tuned radials. The problem being, the footprint of my roof is only 35' x 35'. With the antenna set up in the center of the roof, there will be only a max of 17" to string the radials outward. I'd have to "snake" them in order to fit and figure out how to secure them. Another draw back is that verticals tend to be noisy. Not to mention shelling out money for a roof mount set up and putting lag bolts in up there.

2. Set up a GAP Titan on a roof mount approx 30-35 feet up. No radials needed with that antenna, but I have been told/read that unless perfectly assembled, they don’t work as advertised. Again... Verticals can be a noisy and the set up time and cost.

3. Set up a Chameleon V11 or v12 vertical rigid diepole on a non conductive mast mounted to brackets on the side of the house with the feed point of the antenna being about 25 to 30 feet high. This antenna is advertised as a "dipole" and does not need any radial set up. There have only been a few reviews of this antenna. All are very favorable, but is it too good to be true??? A vertical mounted rigid antenna working with no radials even if it is being called a dipole ??? With this antenna, I’d be able to avoid having to use a roof mount. Just mast it to the side of the house high enough for the bottom pole to clear the roof. A simple install. Still… No idea at all how good this antenna is.

4. Go with a wire antenna. I had in mind using the Buckmaster off center fed diepole. The eight band 300 watt version has two pole lengths of 90' and 180' respectively. I had in mind hooking the center feed point to the apex height of the side of my house to a non conductive hook I can screw in up there. There is enough length of space on my lot to let both the long and short pole ends to extend out

and down in and inverted V. I'd secure the pole ends to the ground with plastic cord and non conductive ground spikes so that the receiving wire was still elevated 8 to 10" above the ground. The feed line would not go straight down from the apex. Since the top of the roof is right where the feed point would be secured, I'd pull the feed up and right on to the roof. From there, run it across the roof and down the other side of the house a few feet and right into the shack on the top floor on the other side of the house. The upside... No ground or radials needed, no expensive or troublesome set up, if need be I can take the thing down in fifteen minutes with no problems at all with just a small hook left on the side of the house. It would also be a more "quite" antenna vs. a vertical like the ones mentioned above. The down side... It would radiate well east and west, but not well off the poles north and south. Also... The very top of the antenna would not be elevated above the house, so about ten feet of each pole up top would be obscured on one side by the house.

I also thought about using my current short-wave listening antenna to transmit with, but I think I'd have to change the matching transformer. I've got an Inverted L with a 30" vertical length and 40" horizontal length. That receiving wire is stranded copper made specifically to be used as receiving wire. It is attached to a matching transformer (an ICE-180) that is mounted to the foundation of my house about two feet off the ground. That ICE-180 is in turn directly grounded to an 8 foot brass grounding rod. The feed line is 50 ohm coax that runs up the side of the house from the ICE-180 and into the shack. The ICE-180 is a "receive only" item and I don't think you can load it up.

Well... That's about it...

Any comments, advice or suggestions would be appreciated.

Thanx in advance.

Michael

1515. Re: odd coax connector

That link didn't work, but is this the one you meant to publish?

http://www.pasternack.com/pdf/catalog/ConnectorIdentifier.pdf

73
John VK2KC

> Anyone know what type of connector this is ?

Two suggestions come to mind. First, have you tried Pasternack's
connector identifier PDF (www.pasternack.com/pdf/catalog/
ConnectorIdentifier.pdf) or equivalent? Second, could it be a damaged
BNC-to-N? It seems strange to have the pin sticking out that far; it
would be inviting damage to the pin.

Cheers,
Tom

It could work pretty well as far as verticals go,
but all the tuned radials will be a pain to deal with
for all bands. It would be easier to ground mount, but
of course, being the antenna is lower, the local space
wave on the higher bands will not be as strong as elevated.
But it will make little difference on the lower bands
as long as you plant the ground radials. One plus to the
ground mount, is the radials don't need to be tuned.
They can be any length and still help. Where as elevated,
untuned radials that are not in use are fairly useless.

Never tried one. But it wouldn't be in my cards if I
were in your position. Also, verticals are no noisier
than any other antenna. It just depends on the polarization
of the noise signal. Noise is RF just like any other signal,
and follows the same rules.

New one on me.. Never have seen one.. Sounds like a
typical half wave design..

>

I'm not a fan of off center fed dipoles.
But overall, I think a wire antenna is your best
choice if you want a decent NVIS signal on the
lower bands.
But... I would use a center fed dipole.
If you require all bands, I would use the
largest dipole you can squeeze in, preferably
80m size, "60-65 feet per leg", and feed it
with ladder line, and using a tuner at the rig.

Myself, I prefer parallel coax fed dipoles, but
I usually don't run every single band.
IE: I have 80 and 40 dipoles on the same coax
feed. I'm on one of those bands 90 percent of the
time. I can slap a tuner inline if I want to
work one of the other bands. Some loss, with it
still usually works well enough to talk.

> you can load it up.

An inverted L can work fairly well in some cases,
but you would need to rework the feed system to
transmit. And a ladder line fed dipole would probably
outplay it anyway for most all bands.

>

Anyway, my vote is ladder line fed dipole for all
bands 80-10. Will need a tuner though.. Or use Cecils's
tunerless method with cut feed line lengths.

I purchased a 10 element 2m Yagi and installed it today. I can now hit
the repeater in question full quieting. The other benefit is I can hit
the one other repeater that I could not even hear before. I am quite
happy now. :-) Now I don't have to cut down any more trees, other than
those I am selling.

Thanks for all the input from everyone. Problem is solved!

This is vintage "Reflections" stuff Walt, where you try to explain what is happening with one foot in the time domain and the other in the frequency domain.

> To begin, the stub generates a new, secondary,
> canceling reflection that cancels the primary reflected wave generated
> by the mismatched line termination.

I can see you heading to re-re-reflections etc.

Thing is that in the steady state (and your Smith chart works ONLY in the steady state), the reflection on the first mentioned (lossless) line (with the 150 ohm load) is determined entirely by its characteristic impedance and the load impedance. The ratio of V/I looking into that line section is given by those parameters and line electrical length.

Sounds boring, but the reflection on the second mentioned (lossless) line (with s/c termination) is determined entirely by its characteristic impedance and the load impedance. The ratio of V/I looking into that line section is given by those parameters and

line electrical length.

The ratio of V/I at the node where both lines are joined is given for a shunt stub by the inverse of the sum of the inverses of V/I for each.

You can think about reflections from on line entering the other, and energy sloshing around, but the Smith chart is not going to help you because is is simply a graphic computer for finding Gamma, calculating Gamma along the line, adding B, G etc by following lines of constant G, B etc.

If we tried to explain the common microwave three screw tuner using re-reflections, virtual open circuits to rearward traveling waves, conjugate mirrors etc, total re-reflection etc, we would complicate something that is easily explained using a Smith chart (and the underlying maths - The Telegrapher's Equation) and quite conventional AC circuit theory.

In fact, a three stub tuner with practical (ie lossy) lines can be explained fairly easily using a Smith chart, even if a little fiddly iteration is needed to deal with lossy elements.

If the total re-reflection etc concepts are hard to translate from mental models to mathematical expressions for simple scenarios, they become near impossible for more complicated topologies and 'real' components.

Owen

Thanx for the response... I myself and leaning the way of the wire die
pole. It appears to be not only the most economical solution, it will
probably give the best results. i also did consider a ground mounted
43 foot DXE Thundebolt MBVA 1UP

> My critics say that a rho = 1.0 cannot be established when the virtual
> short is caused by wave interference.

A reflection is what happens to a single wave at an impedance discontinuity. The redistribution of energy associated with interference is technically not a reflection since it involves the superposition of two (or more) waves. As a result, reflection mechanics cannot be used to explain interference effects. The "virtual short" is the *result* of the combination of physical reflections plus conditions associated with interference, i.e. the "virtual short" is not the *cause* of anything - it is the *result* of reflections plus interference.

Most people deal only with reflected voltages where the interference is transparent. When we start dealing with reflected power, interference is NOT transparent as it must be recognized to be able to track the energy through the system.

If we superpose two identical waves of 100 volt at zero degrees, we obviously get 200 volts at zero degrees. However, when we recognize that in a 50 ohm environment some distance away from any source, we have taken two 200 watt waves and created a single 800 watt wave, the question arises: Where did the extra 400 watts come from? The answer is from constructive interference which requires 400 watts of destructive interference in the opposite direction in order to satisfy the conservation of energy principle. When interference is involved the virtual power reflection coefficient may not be the square of the physical voltage reflection coefficient.

Hiya...
Newly minted ï¿½non technicalï¿½ ham here :-)

Been a SW DXï¿½er for many years and decided to get my ham ticket
recently.

Now that I've decided on what to get for my first ham radio, (TS-590s)
I'm moving on to deciding on an antenna. The goal will be DX'ing the
ham bands with phone and eventually CW. I'm looking for an antenna set
up that will work on 10 to 80 meters. Of course, multiple specific
antennas would be an ideal, but that is not in the cards. I've had a
few options in mind. All of course, would be coupled with an antenna
tuner if the internal auto tuner on the radio cold not do the job.

Any comments, advice or suggestions would be appreciated.

Thanx in advance.

Michael

Dear Michael: Let us know your call-sign when it arrives.
I too recommend a wire dipole with equal lengths of wire each side of a
ladder-line feed. Avoid the use of so called 4:1 whatever. Consider
finding a 275 Watt Matchbox (a larger item also exists). It is ideal for
efficiently coupling energy from a coax transmitter to ladder-line fed
dipole.

Work on mastering CW as that may be the most effective way to make DX
contacts with low power and a low antenna.

Enjoy. 73, Mac N8TT

The first antenna you buy or build will be a disappointment.

Bigger is always better than smaller with an antenna. We all
eventually learn that.

A multi band antenna is like a Swiss Army Knife. (I use both!) They
are very handy, but it is always easy to find a better solution to the
task at hand.

Cautiously imitate the success of others before you get too serious
about innovating. There are reasons why some antennas or equipment are
or are not popular.

Locally here in Central North Carolina the recommendation to new Hams
is what is known as the G5RV antenna. There are a lot of respected
vendors who offer G5RV's at competitive prices. You will need some
kind of tuner sooner or later.

Get on the air! Find out what direction you really want to go.

Let me try an example in ASCII to see if it can work.

--50 ohm--+--1/2WL 291.3 ohms--50 ohms

Given: The steady-state forward power, Pfwd1, on the 50 ohm line is 200 watts. The steady-state reflected power, Pref1, on the 50 ohm line is zero watts. 200 watts of steady-state power is delivered to the 50 ohm load. The power reflection coefficient, rho^2, is 0.5 at point 'x' and at the load. The power transmission coefficient, 1-rho^2, is 0.5 at point 'x' and at the load.

The steady-state incident forward power, Pfwd2, at the 50 ohm load is 200/0.5=400 watts. The steady state reflected power, Pref2, at the load is 400(0.5)=200 watts.

There are four superposition components:

1. The component power reflected from point 'x' back toward the source is Pfwd1(rho^2)=200(0.5)=100w.

2. The component power transmitted through point 'x' in the direction of the source is Pref2(1-rho^2)=200(0.5)=100w.

The fields of these two component waves are 180 degrees out of phase and they are equal in amplitude so they cancel to zero. Note that Pref1=zero. This is 200 watts of total destructive interference. The conservation of energy principle says that, in the absence of a nearby source (which this is), any destructive interference must be offset by constructive interference in a different direction. In a transmission line, there are only two directions, i.e. destructive interference in the direction of the source must necessarily be offset by an equal magnitude of constructive interference toward the load. That's exactly how Z0-matches function from an energy standpoint. Addition of EM wave powers are accomplished by the irradiance equation from the field of optics.

Ptot = P1 + P2 + 2*SQRT(P1*P2)cos(A)

where A is the angle between the two electric fields associated with the two waves.

Pref1 = 100w + 100w - 200w = 0, where the -200w is destructive interference (negative sign).

3. The component power transmitted through point 'x' in the direction of the load is Pfwd1(1-rho^2)=200(0.5)=100w.

4. The component power reflected from point 'x' back toward the load is Pref2(rho^2)=200(0.5)=100w.

The fields of these two component waves are in phase and they are equal in amplitude so they add to double the voltage and current magnitudes. When we double both the voltages and currents, we multiply the power by a factor of four. Thus, two 100 watt waves result in a single 400 watt wave when they engage in total constructive interference as they do in the above example.

Pfor2 = 100w + 100w + 200w = 400w, where the +200w is constructive interference (positive sign).

|destructive interference| = |constructive interference| and all is well with the conservation of energy principle.

Note that the physical power reflection coefficient is 0.5 everywhere. However, Pref1/Pfwd1=0, i.e. the virtual power reflection coefficient is zero (same as the single-port reflection coefficient).

All of the power reflected from the load, Pref2, is redistributed back toward the load at point 'x', i.e. the virtual short, virtual power reflection coefficient is 1.0 even though the physical power reflection coefficient is 0.5 at point 'x', i.e. A single-port analysis yields a power reflection coefficient of 1.0 looking back into point 'x'.

Walt is obviously using a single-port analysis where *everything is virtual*. Impedances are V/I ratios, not actual devices. Thus the Pref/Pfwd power ratios are virtual. The difference between reflected energy and interference energy is the difference between real-world reflection coefficients based on real-world impedance discontinuities and virtual reflection coefficients based on V/I ratios and Pref/Pfwd ratios.

Walt, here is my humble opinion of what the problem is:

1. You are considering that virtual impedances and virtual reflection coefficients exist in reality to the point that they can be the cause of something. IMO, everything virtual is a result, not a cause. That's why it is called "virtual".

2. You are considering the redistribution of reflected power back toward the load to be 100% caused by reflections governed by reflection mechanics. IMO, that is OK for a voltage analysis, where energy considerations are completely transparent, but definitely NOT for a power analysis. When power is being considered, the difference between reflected energy and interference energy MUST be taken into account because INTERFERENCE ENERGY DOES NOT OBEY THE RULES OF REFLECTION MECHANICS. It obeys the rules of interference mechanics.

3. The assumption that all sources are non-dissipative is a convention that I was taught in college. My professor emphasized that it is a *convention*, convenient for analysis, but not necessarily true in reality. Thus it is assumed that any reflected power that is absorbed by the source was never generated in the first place. But that is a *convention* to make the math easier and not necessarily what happens in reality.

4. The V/I ratio that is your mismatched source impedance is indeed non-dissipative but is most likely a combination of reflections and interference caused by reflected energy flowing into the source and superposing with the generated wave. IT IS SIMPLY IMPOSSIBLE FOR REFLECTED ENERGY TO SIMULTANEOUSLY BE THE CAUSE OF A VIRTUAL SOURCE IMPEDANCE WHILE BEING RE-REFLECTED FROM THE SOURCE TERMINAL, i.e. it cannot be used at the same time for two completely different purposes at two different locations. Somewhere back inside the source, it is likely that dissipation of reflected energy is occurring in any mismatched system.

I have said this before and it fell on deaf ears. Since RF energy cannot travel faster than the speed of light, the only way that a source can know the value of its load impedance is in the form of feedback of *reflected energy* from the load, i.e. unless the load impedance is equal to the source impedance, REFLECTED ENERGY MUST NECESSARILY BE FLOWING INSIDE THE SOURCE FOR THE SOURCE TO DETECT THE VALUE OF ITS LOAD IMPEDANCE. The reason for confusion about this subject is that the lumped circuit model presumes instantaneous, faster than light speed, throughout the universe. This faster than light concept is set in concrete brains throughout the RF engineering world. It is indeed strange that RF engineers using the lumped circuit model, don't realize that it takes about one ns for a source to detect a load that is six inches away. The V/I ratio from the source changes after one ns when the first reflected energy arrives. The source has absolutely no way of detecting its load impedance until the first reflected energy arrives. Any other concept is just magical thinking about the real world.

Here is a special case example where all of the steady-state reflected power is dissipated in the source resistor. This particular source was presented by w7el in his food-for-thought series.

Sorry Owen, my data above that you say is wrong is not wrong. I'm absolutely astounded that you would say so. You have misconstrued my data to make such an assertion. I calculated the data and then plotted it on the Smith Chart, which verified the data as correct.

So that other readers will understand how I calculated the data I'll begin with the 150-ohm load terminating the 50-ohm line, yielding a normalized impedance of Z = 3 + j0. Moving along the line toward the source the line impedance changes, arriving at a point where normalized line impedance is 1 - jX. The reactance X is determined by the SWR on the line which is 3:1. jX = 1/(sqrt SWR/ SWR - 1), which yields jX = -1.1547 ohms. This value of jX is verified by drawing a radial of 3:1 SWR to intersect the unit-resistance circle on the Smith Chart. By inserting an inductive reactance jX = +1.1547 ohms in series with the line at this point cancels the line reactance, making the normalized line impedance 1 + j0, where it was previously 1 - j1.1547.

Inserting the inductive reactance at that point causes a discontinuity in the line that generates a second reflection, a canceling reflection that cancels the primary reflection, thus establishing an impedance match at that point.

Now where is the impedance-matching point on the line? First we find the voltage reflection coefficient of the normalized impedance at that point, which is rho = (Zo - Zx)/(Zo + Zx) = 0.25 - j0.43301, which

when converted to polar form, rho = 0.50 @ -60°. Extending the radius through the 3:1 point on the unity-resistance circle on to the periphery of the Smith Chart, it lands on the -60° point, which again confirms the validity of my data that you assert is wrong.

Owen, you are a brilliant and an excellent lecturer. But I don't believe I need a lecture on impedance matching with transmission lines. So just on one point, where have I inferred that I was not working in the steady state?

Walt, W2DU

I forgot to mention in the above post that the -60° on the Smith Chart periphery is the angle of the reflection coefficient, which is twice the value of the electrical length. Therefore, the matching point is 30° from the load toward the source.

> Now where is the impedance-matching point on the line?

By definition, the Z0-match point is where the reflections toward the source are first eliminated, i.e. Vtot/Itot=Z0, which is on the source side of the inductive stub. If reflections were eliminated anywhere else (closer to the load) then there would be no need for that section of feedline. An energy analysis is possible but would no doubt be messy. For instance, what is the SWR at the stub short? Where is the ground reference at the stub short? Since the series stub is a certain number of degrees long, the two currents at the mouth of the stub cannot possibly be 100% differential, i.e. common-mode currents exist on the series stub. Since there is a phase shift in the series stub that doesn't exist in the main coax braid, common-mode current must be flowing in the rest of the system. Electrically, how long is the series stub in degrees? Does an impedance discontinuity exist at the short at the end of a series stub like it does at the end of a shorted stub - or not? What is the characteristic impedance of a series stub? (It is probably not the Z0 of the transmission line being used.)

There is obviously a multiple-port impedance discontinuity at the Z0-match point but I don't know what it is or how to measure it. I don't even know how to measure the multiple-port s11 at the Z0-match point. IMO, this example is just too complicated for 99.9% of the readers here, including myself.

If we put the series stub (or inductive coil) into a two-port black box and performed s-parameter measurements on it, we could come up with the s-parameter equations.

Source--50 ohm line--x--black box--y--150 ohm load

Reckon what s11 we would measure if we replaced the 150 ohm load with a 50 ohm resistor?

By my calculation, the normalised line resistance at that point is 1.

You acknowledge that a couple of lines later when you said "...for a line impedance of 50 - j57.735 ohms", hence my further comment to that effect.

> absolutely astounded that you would say so. You have misconstrued my

I don't think so Walt, I think you have made a typo you haven't yet seen.

That was a sidetrack, as Walt's example is a series stub and in that case, the V/I looking into the series combination is simply the sum of V/I for each.

verticals have gotten a bad rap, they are considered noisy only
because most people who don't have room for anything else put one up
on their roof or back yard where they are often near noise sources.

no, don't transmit through the ice180, it is for receive only.

since the ts590 has a built in tuner just throw up as long a dipole as
you can fit as high as you can get it and get on the air... any
antenna is better than no antenna, and you can make a dipole as good
as any you can buy at much less cost.

Yep. Thanks, John. I'm not sure HOW I managed to do THAT! I thought I copied-and-pasted, but something got messed up. Hope your revised URL helps others looking for connector info.

Ralph: I wonder if it's a specially modified N for some weird application. I've seen UHF connectors modified with the center taken out so that RG-213's center conductor and dielectric can be extended, for use in connecting high voltages. Your adapter sounds way different than that, though.

Cheers,
Tom

Owen, are you still saying my data is wrong? And that I've made a typo that I missed? I can't believe I'm reading this. So please tell me, where is that typo? And please explain further where you believe I've made an error in calculating the data--I don't think so.

And for Cecil, you're worrying about common-mode currents on my series stubbing? I mentioned in a earlier post to not worry about it, because my series stubbing was used only as a tool to explain how the canceling wave is formed, and was not intended as a practical procedure for matching a line.

This is inconsistent, if I normalise 50-j57.735 I get 1-j1.155.

The first line of the quote is correct IF you replace the work resistance with reactance, otherwise it is wrong.

Best states early in his article "In this and the two subsequent articles, Thevenin equivalent circuits are used in the analysis of the wave reflections
that occur within a transmission-line system. A Thevenin-equivalent circuit consists of a constant-voltage source, VS, and an equivalent series output impedance, ZS. This equivalent circuit is not intended to be an accurate
physical representation of the output stages of a transmitter. However, the Thevenin-equivalent circuit can be used to illustrate concepts associated with the wave-reflection mechanics that occur within a transmission-line system
and specifically at the output terminals of a transmitter."

Whilst acknowledging that the Thevenin equivalent is not intended to be an accurate representation of a transmitter, he goes on to assert that it can be used to illustrate what happens in a network with a transmitter.... so to me, it seems that the one thing that has been readily dispensed with in this application is accuracy.

His equation 8 seems to me a development of why / how steady state is established in a context where the source is validly represented as linear, one where Gamma is independent of V and I at its terminals.

A long time ago, I was showing people how to align microwave filters using Return Loss (RL) measurement as the indicator of filter response. So, we had a sweep generator (with tightly controlled equivalent source impedance of 50+j0 ohms), to a circulator with filter on the next port and a crystal detector on the next port. The filter was terminated in 50+j0, and the filter was aligned for a specified RL response over a frequency range.

I questioned in my own mind at the time whether measurement of the reflection only was indeed measuring RL, we had not proven that the forward wave was constant with frequency and load impedance. This question was answered by a quite simple analysis that showed that the forward wave component wrt some Zo=Ro was constant if the source impedance was validly represented as a Thevenin source with source impedance equal to Zo. Since these sources have controlled source impedance, usually by way of a large attenuator at the output port, there was no need to measure the forward wave vs frequency, a single measurement with the filter port of the circulator terminated in a s/c provided a correct baseline of RL=0dB for the subsequent filter measurement.

Applying that knowledge to the case of a transmitter, if you were to connect a directional wattmeter between a HF ham transmitter and a variable impedance load (eg an ATU followed by

a dummy load), and vary the load impedance, changes in observed 'forward power' suggest that the transmitter is not well represented as a Thevenin source with Zs=50+j0 ohms. In my experience, the results of this test vary from transmitter to transmitter, but even with a single transmitter, vary with power level, different sensitivity to changes in R and X components of load Z, and frequency.

>Anyone know what type of connector this is ?

It's an ordinary BNC to Male N adapter, where the dielectric has been
somehow mangled, causing the center shield, pin, and dielectric to get
pushed out. You might be able to disassemble the adapter and repair
it. Try pushing on the center pin on the N side of the adapter and
see if it moves back into the adapter. Some of the cheap connectors
from China are little better than junk and tend to fall apart with
little provocation.

Hint: Photos are useful for identifying strange connectors.

You're right about the resistance vs reactance blip. That wasn't a
typo but a thought aberration. Sorry I didn't catch it.

But no, Owen, 1.1547 is correct from the equation. Increasing to seven
significant figures it's really 1.1547005. If you set your calculator
to three significant figures and divide 57.735 by 50, you get
1.1455, true. But if you set it to five significant figures you still
get 1.15470, and you're quibbling about the round-off error? The
precise figure is obtained from the equation, not off the Smith
Chart.

Ok, well whatever it was, it was wrong as I said, but you have got it now!

It was not about precision, it is not about round off errors, it is the statement that "normaised resistance is 1.1547" when it is actually 1, normalised reactance though is 1.1547.

The comment was a byproduct of my reading and working through what you wrote, trying to understand it.

The other thing that was mentioned in discussion is the "non-dissipative resistance" which you seem to think must give rise to Gamma=1 at the source. This "non-dissipative resistance" seems an invention that is quite flexible, quite convenient, because it seems that some posters regard radiation resistance as a "non-dissipative resistance" yet they have not argued that Gamma at the antenna equals 1.

For some reason, Google Groups won't let me see any postings to this thread past June 13th. If anyone has asked me any specific questions related to my post about that time (which I also can't see now), my apologies for not answering. Maybe Google will fix this, but I rather doubt it. I suppose I'm better off not knowing what all is going on anyway.

Cheers,
Tom

Indeed, I am a brandy new Technician... I plan to upgrade to General in short order. I decided to space the tests out a few months appart as I learn. I already knew a good deal of what was on the Technician exam from my many years of sw dx'ing and homebrewing. I am also up near eight words per minute with CW, but that is only with the learning program I have been using on my PC. I never actually sent any CW :-) My plan is to get my antenns set up and try some phone on 10 meters where the Technicians are allowed with that mode. I also have a few friends in the area that are hams that I will cut my CW teeth on :-) I dont have much interest in VHF and UHF, so I have every intention of securing my General soon. My real interest is 80 and 40 meter DX. As far as the antenna goes... I've decided to string up a ladder fed diepole. Seems the best way to go for now... Later on a yagi :-)

Thanx for the response...

I actually have a 102' G5RV that I used to use for short-wave listening. Currently, it is coiled up in storage in my basement. I took that antenna down along with a long wire I had after I built the inverted L that I currently use for short wave listening. The inverted L did better across the board than those other two antennas, so I took them down. The G5RV had a decent signal to noise ratio for short wave, but the inverted L I built is considerably better. I'd assume that grounding the matching transformer properly made all the difference. At any rate... I would not used that old G5RV for my transmit antenna because the feed line is only 300 ohms. Since I have decided to go with a wire dipole for starters, I'm moving on now to buy the best one I can find. I don't care to homebrew my first ham antenna... Rather have one that I'm sure works while I'm learning the ropes

Since you decided to start with a wire dipole, consider making or downloading a map centered on your location so you optimize the orientation for whom you want to work. For example, my 20m Field Day dipole will be optimized for 060 degrees, the bearing from Southern California that favors the most of North America. Getting it wrong can cost more than an s-unit.

http://www.wm7d.net/az_proj/ will provide one from your inputs. (I could only get it to print North America just now; probably something I did.)

If you make a resonant dipole cut to length for one band (my preference), its height-above-ground affects its resonant frequency. Close to the ground brings resonance at a lower frequency than the formulas predict, so you'd need to shorten it to bring it to resonance (at that height).

Antennas can be hard work but when you get one that plays well, it's all worth it.

1547. Re: Reflection coefficient for total re-reflection

Newsgroup: rec.radio.amateur.antenna
Date: 2011-06-19 12:43:48 UTC
From: Cecil Moore <w5dxp@hotmail.com>
Message-ID: <164a2099-f77d-4bf3-8fea-dfb82fde00a6@b1g2000yql.googlegroups.com>
Source record: 4498

Here's the mathematical problem with assuming a reflection coefficient of 1.0 at the source output: Let's assume 100 watts of sourced power and 50 watts of incident reflected power in a 50 ohm environment.

Source Wave: V=70.7v at 0 deg, I=1.414a at 0 deg, 100w toward the load.

Incident Reflected Wave: V=50v at 0 deg, I=1a at 180 deg, 50w toward the source.

A reflection coefficient of 1.0 assumes a (virtual) short at the source. A short circuit reverses the phase angle of the incident reflected current during the reflection process so all forward-traveling voltages and currents would have a phase angle of zero degrees. Superposition phasor math becomes simple arithmetic addition.

Re-reflected Wave: V=50v at 0 deg, I=1a at 0 deg, 50w toward the load.

70.7v at 0 deg PLUS 50v at 0 deg EQUALS 120.7v at 0 deg.

1.414a at 0 deg PLUS 1a at 0 deg EQUALS 2.414a at 0 deg.

120.7v(2.414a)=291w, i.e. 141 watts more power than the source power and reflected power combined. Where did the extra power come from?

Conclusion: Assuming a reflection coefficient of 1.0 looking back into the source violates the conservation of energy principle. (The only exception to this assertion is the special case where the incident reflected wave arrives orthogonal to the sourced wave.)

Here's the problem with assuming that a virtual impedance can cause reflections:

A virtual impedance is created according to the following equation using *phasor math*:

Zvirtual = (Vfwd+Vref)/(Ifwd+Iref)

Note: REFLECTED ENERGY HAS TO BE FLOWING BACKWARDS THROUGH THE VIRTUAL IMPEDANCE POINT FOR THE VIRTUAL IMPEDANCE TO EXIST.

How can the same reflected energy be re-reflected while at the same time being used to cause the virtual impedance that causes the re-reflection? Isn't that akin to having one's cake and eating it too?

Don't try to read too much into the antennas. Unless you can get an 80 meter up to around 100 feet, just about any dipole will work. I like the Windom or Off center fed antenn myself for an all around antenna. It just does not work 15 meters or the WARC bands very well.. I have one up and an 80 meter dipole about the same height (about 50 feet) at right angles to it. Not much differance most of the time, but sometimes one or the other will be about 10 db beter.

For 80 meters and up, about 130 to 140 feet of wire fed with ladder line and a good tuner is a good way to go if you want to bring the ladderline into the tuner.

Depending on how much work it it, you may want to put up a 10 meter dipole or if possiable make it out of aluminum conduit or such and make it so yo can rotate it.

As you problay know there is no CW test now. You should have taken the General written test when you took the other one. Should not have cost any more at the time and you may have gotten lucky.

It only took me about 30 years to get my triband antenna up.. I was mainly interisted in weak signal vhf and did have a light weight tower up about 40 feet for that, but it would not hold a triband antenna. Finally moved to another location and put up a good tower to 60 feet with the triband and other vhf antennas.

The problem here Cecil, is that you've made the same error as Steve in believing that the reflected voltage adds to the source voltage at the source to establish the forward voltage. I've proven that it does not, but it's power or energy that adds. Adding the voltages gives the wrong answer--adding the powers does not. (When adding reflected and source voltages you obtain the standing wave, not the forward wave.) When you add the 50w of reflected power to the 100w of source power we get 150w. On the 50-ohm line, 150w breaks down into 86.603v and 1.723a, No extra power to be accounted for, and no violation of the Conservation of Energy Law.

The explanation of this concept appears in Chapter 25 of Reflections 3, beginning on Page 25-3, Col 2, Par beginning with "As mentioned earlier, Steve failed to recognize..." From there on into the math I present on the next page proves the concept to be correct.

Concerning 'virtual' impedances, an impedance is an impedance, whether formed by Z = E/I, or by a physical impedor. Virtual opens or shorts are different animals, established by two conjugately-related reflected waves traveling in the same direction, and arriving simultaneously with the source wave at an impedance matching point. Please read all of Sec 25.3 in Chapter 25, beginning on Page 25-5.

thanx for all the input... when i went to take my technician exam, i got through it very quickly... they graded it and asked if i wanted to take the general exam also... since i had only read the technician manual, i did not take the ve up on his offer to try the general... i plan to get the new 2011-2015 general manual and upgrade in the next few months... in the mean time, i have to work out equipment and set up issues. i've decided on what radio to get (TS-590s) and going with a wire dipole... the next issue is earth ground and lightning protection. my shack is on the second floor of my house. in order to deal with rf and lighting with my short wave set up, i went with an inverted L that is grounded to an 8 foot brass rod through the matching transformer. i dont have any rf problems with this set up even though my radio is not grounded in the shack. for lightning protection, i disconnect my coax feed and hang it out the window when I'm not using the radio. i've already read a pile of stuff on line already about other people that have had the same problem with a second floor location, but I'm still not sure what I'm going to do about grounding the transceiver when I hook it up to a dipole.

Best says at p5-6 of his first article "In all transmission line systems, the level of voltage or wave reflection at either end of the transmission line is determined from the reflection coefficient of the impedance terminating the transmission line. The “re-reflected” voltage, VRER, adds to the initial forward-traveling voltage, VI, and the process of reflection and “re-reflection” continues until equilibrium is reached."

In my view, his statement is incomplete, he does not address the response of the source to the new V/I ratio that exists at its terminals when the reflected wave arrives and is "re-reflected".

As I explained earlier in this thread, if Zs=Rs=Zo=Ro, (proof at http://vk1od.net/transmissionline/VSWR/Zs50.htm) then the forward voltage component remains constant and so, reflected voltage can simply be added to the forward voltage to find the new terminal voltage.

Taking the case of a Thevenin source where Rs=0, terminal voltage V is constant and so Vf must change when the reflected wave arrives at the source, and so Vf is not independent of Vr and so we can say that Vf is not independent of Vr for all Zs, but for the special case Zs=Rs=Zo=Ro discussed in the previous par, it is.

When Best considered the case where Gamma at the source was not 0, then he needed to also consider the source response to the change V/I after the reflected wave arrived at the source. Best does discuss this response of the source to changing V/I in the second article where his SPICE model shows what is happening.

Discussing Thevenin sources driving transmission lines is quite interesting, but it is naive to think that typical RF power amplifiers response to terminal V/I is the same as a Thevinin source. In any event, this is an explanation of how the steady state is established rather than an analysis of the steady state.

What you seem to be saying is that the voltage reflection coefficient is NOT the square root of the power reflection coefficient since if the power reflection coefficient is 1.0, the voltage reflection coefficient would also be 1.0. It seems that would be a violation of reflection mechanics. Is reflection mechanics wrong or did you misunderstand what I (and Steve) are saying?

Walt, I believe we have proven the same thing. But neither Steve nor I believe that the reflected voltage adds to the source voltage at the source. We had this same conversation years ago when I lived at my last QTH and you still seem to be confused about what Steve was saying.

Steve's P1 is *NOT* the source power (as you seem to believe). It is the source power that is transmitted through the impedance discontinuity, i.e. Pfwd1(1-rho^2). His P2 is *NOT* the reflected power (as you seem to believe). It is the reflected power that is re-reflected from the impedance discontinuity, i.e. Pref2(rho^1). It seems you have never understood what Steve was saying. Let's go over it again. The power reflection coefficient at point '+' is 0.5 looking in either direction.

100w Source--50 ohm--+--1/2WL 291.3 ohms--50 ohm load

On the 50 ohm line, Pfwd1=100w and Pref1=0w

On the 291.3 ohm line, Pfwd2=200w and Pref2=100w

Steve's P1 equals Pfwd1(1-rho^2)=100w*0.5=50w

That's the component of source power that makes it through the impedance discontinuity.

Steve's P2 equals Pref2(rho^2)=100w*0.5=50w

That's the component of reflected power that is re-reflected from the impedance discontinuity.

The total forward power on the 291.3 ohm feedline then becomes:

Ptot = P1 + P2 + 2*SQRT(P1*P2)cos(0)

Ptot = 50w + 50w + 2*SQRT(50w*50w) = 200w

And that is indeed the forward power on the 291.3 ohm line.

Please go back and read what Steve said given that his P1 is NOT the source power and his P2 is NOT the reflected power. His power equation comes directly from any optics physics book and is the irradiance equation for EM waves.

Steve did indeed make some errors in part 3 of his articles but the above is not one of them.

Using a dipole, which is a complete antenna, there
is no need to have an RF ground. And no need to ground
the radio, unless there is a high voltage safety reason
for it. "safety ground". But any outlet with a ground
pin will provide that.
With the case of the Kenwood 12v rig, that is not
the case. Only the power supply that feeds it needs a
safety ground. And most all those have a third ground pin
on the plug.
But you do need to worry about lightning. But less with
a dipole, than a vertical that is on the house.
The horizontal wire will be less likely to stream than
a vertical. So less likely to attract a strike.
But it can still happen. It would be best to run the
feed line straight down to ground, and then under or
along the ground to the shack. But this is kind of
impractical with a typical ladder line setup. :(
The worst case for damage is to have the feed line
running elevated in the air to the 2nd floor shack.
So if you have to run it like that, you sure don't
want it connected when storms are in the area.
I'd have some way to totally disconnect it from
the house on the outside when not in use.

This is one reason why I generally prefer coax.
Easier to mitigate the effects of lightning..
I can snub lines to ground at the base of masts,
connect and snub through a "ground window" at the
entrance to the shack, and generally it's easier
to use the typical lightning arresters.
Ladder line is harder to deal with in these aspects.
Or at least to me..

But you can use gas tubes on each conductor, etc..
That would require a good lightning ground outside.
And all grounds outside should route to a central
point, and be tied together to keep all at the same
potential.
If you use a mast to support the apex of the dipole,
it's more likely to be struck than the wire antenna
itself. So it's best to use a metal mast that is
grounded at the base. I don't use any non conductive
masts here.
I have no RF ground in the shack. Except for rare
cases, I don't believe in them. I've found they
usually cause more problems than they solve.
These problems would usually rear their ugly heads
when I would kick in some RF horsepower.. What is not
yet a problem at 100w, can be a real pain at a KW+.
:/

I am restricting that unnecessarily, the requirement is just that Zs=Zo.

More of than not, an instrument that we might use is calibrated for some real Zo, ie Zo=Ro, and so that would mandate that Zs=Rs to observe constant Vf with such an instrument.

Thanx for the input... One of the reasons i was considering an OCF dipole over a ladder fed "ballanced" dipole at first was a matter of lightning protection. With an ocf dipole, i can use 50 ohm coax as the feed line. not to much trouble to use a gas tube. Though, i'll probably stick with my current method and just disconnect the feed line and hang it out the window even if I use an arrestor. i'm also told by a few other people that putting a sharp 90 degree bend in the feedline outside the shack is an old trick that usually helps in the case of a direct strike. i'd gather that static coming down the feedline would probably be the more common worry.

For a voltage analysis, one doesn't need to use power (or energy) at all. Given the proper voltage reflection coefficients, the voltages simply phasor add up to the proper values. The conservation of energy principle is completely transparent during the superposition of voltages. It is the power (energy) analysis that is causing the problems.

Walt, you may be right about reflected power incident upon a source being 100% redistributed back toward the load but it is definitely not due to 100% re-reflection. In any power (energy) analysis, interference effects must be included in the analysis. If the source completely rejects incident reflected energy, it is because total destructive interference is occurring within the source which results in constructive interference toward the load. Here's a reference from my "Worldradio" energy article that explains the interference phenomenon.

"[8] Maxwell, Walter, Reflections II, (c) 2001 Worldradio Books, ISBN 0-9705206-0-3 page 4-3, "The destructive wave interference between these two complementary waves ... causes a complete cancellation of energy flow in the direction toward the generator. Conversely, the constructive wave interference produces an energy maximum in the direction toward the load, ..." page 23-9, "Consequently, all corresponding voltage and current phasors are 180 degrees out of phase at the matching point. ... With equal magnitudes and opposite phase at the same point (point A, the matching point), the sum of the two (reflected) waves is zero."

i.e., a source doesn't have to have a power reflection coefficient of 1.0 in order for 100% of the incident reflected energy to be *redistributed* back toward the load. If total destructive interference is occurring within the source, the power reflection coefficient can have any value between 0.0 and 1.0.

Consider a Zg=50 ohm source driving a Z0=50 ohm 1/4WL ideal shorted stub. The voltage reflection coefficient looking back into the source is 0.0 so the re-reflected power is zero. However, zero power is being sourced because total destructive interference is occurring in the source. All of the reflected power is redistributed back into the stub by destructive interference and none of it is re-reflected, i.e., the

power reflection coefficient looking back into the source is 0.0
because Zg=Z0.

Nobody seems to have asked the burning question that's really important... what's your budget?

As far as kind of antenna, feedline, etc.

You're not going to have an optimum on all bands. For right now, as the sunspots are coming up, the high bands seem to be working fairly well (and as a Tech, all you get is 10m anyway, as far as phone.. but when you get your General or Extra, you'll get the rest.. study and take that test..)

I'm a huge fan of autotuners *at the feed*. You don't have to spend your time trying to adjust the antenna, or worrying about feedline loss, or any of a zillion other things. Sure, there's some loss in the tuner, but it's pretty easy to get the antenna close, and if the antenna is "close" then the autotuner takes care of the rest.

Life is too short to try and prune radials for resonance, and then have it go out of tune when the tree next to the antenna grows, etc.

Folks who have tube amps have the tuner built into to the output network, and they're used to the whole thing of tuning every time they change frequency, so for them, open wire line to their rig is fine. Do the match at the amp end, the loss from mismatch in the line is small because the line is high Z, etc. But that's not typical of a "brand new" station: solid state 100W amp, coax feed, etc.

My own preference is for an autotuner at the feedpoint of some sort of dipole or inverted V. Any of the 10-15-20-40 multi wire band dipoles will work quite well, and with an autotuner, you don't have to worry about "pruning to exact length". The two sides don't have to be equal length, even. Be aware that not all tuners can tune all impedances, and you generally do NOT want a transformer between antenna and tuner (esp if there's a lot of reactance to tune out), so going too far in the OCF

direction may be counter productive. Then you can feed with coax, which is a whole lot more convenient than any sort of open wire line.

Second choice which is less visually obtrusive is some sort of vertical with an autotuner at the base and an adhoc counterpoise of random length wires. Higher the base, the better, in general.

Lightning protection..

Where are you located? A lightning alley like mid Florida? Or somewhere were lightning is an unusual thing (like Southern California)?

Gas tube arrestor is a nice idea. What will you hook the ground on that arrestor to? A stake pounded in outside where the coax comes in? Make sure that you run a bonding wire from the stake to the electrical system ground. A concrete encased grounding electrode is even better (Ufer ground)

Or, if you're not really in a big lightning area, just use the arrestor as a "receiver input overvoltage protector", for whatever good it might do. (I don't know what a TS590 input looks like, but the couple hundred volts from the arrestor might blow it up...). disconnect the coax when your not using it. BTW, short the coax with something and make sure it's not close to something that might catch fire if you do get a lightning hit.

The 90 degree thing is useless.. there's no significant impedance in a 90 degree bend. If you get a direct hit, unless you're spending a fair amount of time and effort on a good system, you're going to get damage..You don't want to spend thousands of dollars on a lightning protection system to protect a 1000 dollar rig.

Static discharge *is* a problem.. but, if you hook the shield to the third wire ground (or that other grounding system), on a dipole, that pretty much takes care of it. Maybe a 100k resistor between the legs (or between the vertical and ground).. Once the center insulator gets a bit grungy, leakage resistance will solve that problem for you.

im in the northeastern most corner of NJ. not exactly lightning alley, but we get storms regularly. about five years ago, one of my radios got fried. i almost always remembered to disconnect my coax and hang it out the window, but the one time i did not, i paid for it. an icom pcr 1000 was left connected to my antenna switch during a storm. i did not even think about it until a few days later, when i went to use the radio. it powered up, but nothing else worked. i sent it to icom and they told me it was a sure bet that static or lightning was the culprit. since then, I have not forgotten to go through my routine :-)

> Gas tube arrestor is a nice idea. What will you hook the ground on that

That is what I had in mind. I already have an 8' brass rod in the ground for my inverted L.

All I have to short a feed line to on the second floor is a metal heating system radiator :-) Probably not the best choice. So... I just let it hang out the wondow when not in use.

> The 90 degree thing is useless.. there's no significant impedance in a

makes perfect sense to me... so... i have always tried to go with
"some protection is better than none". though, many are fond of
saying that "*some* lighting protection = zero protection"

I am telling you, I wasn't worried about much, just retired and enjoying
life, but ...

Now I am back to worrying about getting some income streams going, if
steak goes to $1,000 lb., I want to be able to afford the real stuff!

I don't know who they plan on eating that "SYNTHETIC MEAT" (and, I put
that very, very kindly -- poor dumb japs, I think the radiation is
affecting their tastes buds AND minds!), but it ain't me!

I mean, who'd a thought, they find themselves knee deep in sewage and
they decide to eat themselves out of the mess! Go figure! I mean, I
have to admit, that is "thinking out of the box" -- but right into the
old sewer plant! EWWWWWWWWWWWW! Kinda job security at the old food
recycling plant ... you eat more, there is more waste, you eat more,
more waste ...

Funny thing is, well, not really funny ... just the way that article is written is in the form of the brain washing which usually precedes the actual action(s!)

I guess I am the lightweight here, just the thought and reading that article made me gag ... I thought it would provoke more anger in Americans ... I mean, if you don't get angry about people eating human feces, what is there which could possibly anger you?

I mean, have you ever considered the parasites which commonly inhabit the human gut, not to mention the dangerous diseases, viruses, fungus, prions, etc?

And to think, before this, I was worried about GMO foods and getting them labeled!

Now I am beginning to feel I am up "synthetic food" creek without a paddle!

Regards,
JS

What influence has a metallic boom on a Yagi antenna?
Normally the design is made without taking the boom into
consideration.

http://yfrog.com/janextgen14p

The voltage curves on the parasitic elements have their maximum
in the center. When using a non-conductive beam the situation is not
affected.

With a metallic boom and with the parasitic elements fastened
to the metal would the oscillation pattern be changed?

http://img28.imageshack.us/img28/3096/boommounted.jpg

Do I have to insulate the parasitic elements from the metallic boom
or is it advisable and allowed to fix them with metal fasteners?
Does the connection have to be made electrically good,
or does it not matter at all?

In fact there are both designs used, but probably without further
consideration. Some manufacturers use plastic holding clamps
for mounting the elements, for no other reason than saving time
during assembly. Other manufacturers just drive a self cutting
thread screw through everything.

The YAGICAD software does talk about mounting elements
on the boom, and NEC is too difficult for me to understand.

Thank you in advance for your answers, and a sixpack
will be kept ready to compensate your efforts at your next visit.

No necessarily, but it is common to design for a non-conductive boom and then make a correction to element lengths for the type of boom in use.

That is not true.

> With a metallic boom and with the parasitic elements fastened
> to the metal would the oscillation pattern be changed?

Depending on how the boom is or is not bonded to the element, and the geometry (sizes, position etc), the conductive boom may reduce the magnetic flux nearest to the element, effectively reducing its inductance in the middle area, so tuning it higher.

> Do I have to insulate the parasitic elements from the metallic boom

If the 'connection' has infinite R (ie no connection) or zero R, there is no power converted to heat, otherwise you invite conversion of RF energy to heat.
>

Not by competent designers, they consider the effects of the boom.

Hello Helmut,

There is influence, whether or not the elements are electrically
connected. When (thickness of the boom) << (element length), the
influence is negligible.

When the above isn't met, you may experience a noticeable shift in
design frequency (it will go up). when connecting the elements to the
boom, the influence will be more. So to compensate for this, the
elements should be somewhat longer. Note that it also depends on where

the metallic contacts are. An element through a boom will experience more shift then an element having just a single-point electrical connection to a boom.

When you have bad connections (for example due to corrosion or a loose nut), movement (induced by wind) will change the electrical characteristics in a time varying way. This may result in cracking noise, even on strong signals. Clean strong signals may introduce noise at other frequencies due to the time varying change in antenna properties.

This may be a reason for manufactures to use non-contact mounting of beam elements. I saw several UHF yagis (with relative thick square booms w.r.t. element length) with loose elements making (bad or no) contact with the square boom. So if you decide to make electrical contact, make sure it is long lasting.

Here you may find useful info http://www.qsl.net/yu1aw/Misc/vhf_ant.htm

With kind regards,

Wim

Thanks, and also thanks to Owen,

I made an error in the description
http://yfrog.com/janextgen14p
because those are current curves, not voltage.

What I learned is, a metallic boom requires a small +length correction
of the dipole elements. YAGICAD does it automatically with a cryptic
value called L+BCF (boom correction factor?)
An electrical connection with the metallic boom will need more
correction than an isolated element mount, if I am correct.

A metallic boom should also affect dipole spacing,
but to what extent, I do not know.
YAGICAD does not care for that, or does it?
Am not sure.

Yes, that is correct. I failed to equate the 60 deg angle of the
reflection coefficient at the point of observation, which is ~.167
wavelengths (30 deg) from the load. Thanks for keeping me straight.
Sincerely, and 73s from N4GGO.

If you Google for "boom correction factor", you should find a wealth of discussion on the subject. It is not all cut and dried, it remains an area of active research.

Yes.. not a lot, but important on a high gain antenna (one that is "super directive".. i.e. has gain > N, where N is number of elements) because the amplitude may not change much, but the phase might, and small phase errors ruin the nulls in the pattern, which degrades the overall directivity.

A modeling program like NEC can easily show the difference.

>
> http://img28.imageshack.us/img28/3096/boommounted.jpg
>
>
That's the distribution of the voltage, but your picture doesn't show phase and magnitude, which is what's important.

There are a whole variety of techniques to account for the boom in a model, ranging from actually modeling the boom (tricky with some modeling codes) to empirically determined correction factors.

>
> Do I have to insulate the parasitic elements from the metallic boom

It does matter. What you really don't want is something that changes. Either always connected or always insulated is what you want.

>
>

basically, a directive antenna gets its directivity from having different phase and magnitude of current in each of the elements. In a Yagi-Uda, only one element is driven, so the current in the other elements comes from mutual coupling among the elements.

That coupling is affected by the spacing, length, and diameter(s) of the elements, so having the boom connected is sort of like having an element that is somewhat "fat" in the middle. It's slightly different.

On a 3 element wideband Yagi, the "boom correction" is going to be pretty small. But on a 432 MHz moonbounce array with 20 elements, and where you want very low side/back lobes to keep the noise temperature down, it gets more important.

back before computers got fast and cheap, there were a lot of analytical (or semi-analytical) approaches to designing Yagi antennas. You'd have an approximation of mutual coupling (from, say, King) and form a matrix equation. You'd figure out what element currents you wanted for your pattern, and iterate your element lengths and spacings until it all worked out. (or, you use the matrix equation to determine the element currents, given the excitation, and then calculate the pattern from that, using simple phased array techniques).

The problem is that simple approximations like King's typically assume constant diameter elements. So, by dint of a bunch of empirical work, people found "correction factors" that you could apply to an idealized model (no boom) that would make it work ok on a boom.

basically, it's all about coming up with a simple algorithm to allow the use of a simpler modeling code (i.e. model without boom, apply BCF, done).

It all depends on what is "good enough". On an HF beam, the elements typically sag a fair amount, and wave around in the wind. Furthermore, the boom is a tiny fraction of the element length so it has a "small" effect (e.g. 10cm boom on a 10m long element) . So the uncertainties in performance due to other mechanical factors are bigger than the effect of a boom.

On a 432 or 1296 yagi using a 2cm square tube as the boom, though, this is less the case. The elements are rigid, 2cm is a big fraction of a 35 cm long element. And, on VHF/UHF, one typically has a LOT more elements and a LOT more gain, so the tolerances on everything are much tighter to get the desired performance. If one were build a 5 wavelength long 20m Yagi (5 lambda isn't unusual for 2m or 70cm), you'd be worrying about those sorts of effects too, at least if you wanted to get the 17dBi gain that might be possible.

An interesting experiment might be to cast the upper elements above a metal slab of 1/4 wave depth which extends a full wave out in all direction of the compass, in eznec/nec/mmana, and serves the purpose of the lower elements connected to a huge boom.

A comparison between a standard yagi and such a design should show a stark comparison of the importance/function of the lower/ground elements, between the two. Or, perhaps just the extension of the boom in the frontal and trailing directions would provide usable data.

In any case, I suspect the influence of the boom, in such a greatly exaggerated example, would be exposed in more defining light ...

What could be done to the upper elements, reflector(s) and director(s), to provide such a comparison(s) is a matter which provokes thought ...

Frankly, I don't even know if any antenna modeling software would allow such an "abuse."

You might want to travel a little. Most of the links to exotic foods
that I posted were from foreign countries. What we consider inedible
is common elsewhere. For example, in the west, we don't eat bugs
(insects). Yet, the rest of the planet has no problems with bugs.
With our present path toward inevitable doom, it's likely that some
manner of famine might become reality. It's then that we'll need to
expand our list of acceptable foods, or starve. If you've ever
survived a survival class, you'll understand the problem.

>I mean, have you ever considered the parasites which commonly inhabit
>the human gut, not to mention the dangerous diseases, viruses, fungus,
>prions, etc?

Sure, and that's the problem. With farm animals, it's a fair
assumption that the animals feces came from a fairly healthy animal.
With human waste, it's not such a great assumption. The extra junk
found in human feces are not easily processed. (Drugs, Bugs, and
Slugs; also known as medicine, bacteria, and parsites). While it can
be cleaned up with a mix of chemical and alpha-particle sterilization,
that makes it too expensive to be useful. I suspect that's where the
high cost of processing mentioned in the article originated.

>And to think, before this, I was worried about GMO foods and getting
>them labeled!

Known problems are not worth worrying about. It's problems that are
currently unknown or un-discovered, that are the real problem. That's
the real problem with GMO. We don't know what eating them will do,
therefore, we assume that it will be bad, and should avoid it.

>Now I am beginning to feel I am up "synthetic food" creek without a paddle!

We haven't even started talking about mining hydrocarbon compounds,
and cracking them into edible substances. Coal tar derivatives are
just the beginning. You could easily eat coal, with the appropriate
flavor and texture additives.

;-) Well, I'm not sure if you also sent that to my email address; I didn't see it there. And of course, I didn't see it here, since I never "sort by date" -- at least not till now, when I've managed to find a free newsgroup server where I can see the messages.

I'm happy to see that Owen has jumped into the thread with his usual well thought out postings. Measuring S-parameters (which includes reflection coefficients) and using them in calculations has been the topic of a great many articles. There are some good Hewlett-Packard notes on them that I believe you can get from the Agilent website, and if not there, from other archives. HP AN95-1 and HP/Agilent AN154 are a couple, but Googling "S Parameter Application Note" will get you lots more. Honestly, I'd have to say they are a better place to try to learn this sort of thing than threads here...

Cheers,
Tom

Available at:

http://www.sss-mag.com/pdf/an-95-1.pdf

One interesting thing about the s-parameter equations is that if one
squares them, one obtains the irradiance (power density) equation from
the field of optics. For instance:

b1 = s11*a1 + s12*a2

are the normalized voltages where b1^2 is the reflected power toward
the source. Squaring the right side of the equation uncovers the
interference term, 2*s11*a1*s12*a2. If that term is positive, the
interference is constructive. If that term is negative, the
interference is destructive. Zero reflected power toward the source
indicates total destructive interference toward the source and that is
the goal of tuning a system to zero reflected power incident upon the
source.

I'm having a tough time visualizing what you're describing. Half
elements sticking up from a "perfectly conductive plane"?

IN general, the boom extending front or back doesn't make a big
difference. If I had to "rule of thumb" it, I'd say that the
"influence" of the boom is several element radii.

Step right up and fire up that copy of HFSS or ADS

in most modern codes you can model *anything* given sufficient time to
build the model and run it. If you have lots of big chunks of "stuff" a
method of moments code like NEC might not be the best choice. One of
the FDTD or similar codes might be better.

A slab of aluminum 1/4 wave deep and extending a full wavelength is all
directions is about as perfect a conductor/elevated-pseudo-ground as I
could ever imagine ... yep, you pictured it correctly ...

Certainly for the front director, and back reflector, it would look as
two legs of the ground plane from a vertical ground plane antenna --
with the bottom dipole element still attached ...

Having all the antenna I want, at this time, I am just too lazy to load up mmana and see the results ... most run-of-the-mill and been-around-forever antennas have pretty much been optimized for cost of materials/work to benefit ratio ... I don't think I have seen anything new, or even claimed to be new, in decades ... or longer!

Let's return to an earlier example and compare a single-port analysis
with a dual-port analysis.

100w
source--50 ohm--+--1/2WL 291.4 ohm--50 ohm load

The 50 ohm Z0-match point is at '+'. The forward power on the 50 ohm
line is 100 watts and the reflected power on the 50 ohm line is zero
watts. The forward power on the 291.4 ohm line is 200 watts and the
reflected power on the 291.4 ohm line is 100 watts. 100 watts is being
sourced and delivered to the 50 ohm load.

The voltage reflection coefficient, rho, at the load is (50-291.4)/
(50+291.4)=0.7071. The power reflection coefficient, rho^2, at the
load is 0.5, i.e. half of the power incident upon the load (200w) is
reflected (100w). Since the load is a single-port, these parameters
are consistent with a single-port analysis. In a single-port analysis,
we cannot tell the difference between a virtual reflection coefficient
and a physical reflection coefficient.

The problem comes when we use a single-port analysis on the Z0-match
point. Since the reflected power on the 50 ohm line is zero, a single-
port analysis would yield rho=0.0 and rho^2=0.0 when viewing the Z0-
match from the source side. When we perform a dual-port analysis, we
get different values for rho and rho^2, i.e. we get the complement of
the reflection coefficients at the load which is a characteristic of
any simple Z0-match similar to the above example.

For a dual-port analysis, rho looking into the Z0-match from the
source side is (291.4-50)/(291.4+50)=0.7071 and rho^2 looking into the
Z0-match from the source side is 0.5, the same as at the load. Looking
back into the Z0-match from the load side, the sign of rho is negative
just as it is at the load with rho^2=0.5, the same as at the load.

Since the two analyses yield different values for the reflection
coefficients, which analysis is correct? The answer gives the clue to
the resolution of this discussion.

I think you're generally right. What the tools give you is the ability to make a "semi-custom" design that's optimized for a purpose slightly different than everyone else.

For instance, you might want a 20m Yagi that's optimized for 14.300 as opposed to 14.050 or something.

Various and sundry multiband schemes also come to mind. Lots of alternatives for element layout, lots of potential interactions. And these designs are not well accommodated by analytical techniques or cut and try on the physical article (because of the interactions at frequencies well away from the resonant frequencies of some elements). Doing something like a Force-12 C3 tribander by cut and try would be tedious at best.

In the VHF/UHF world, where very high directivity is the rule, and people worry a lot about side/back lobes (for antenna noise temperature reasons), and because the structure is significant in size compared to the elements, I think modeling codes are almost essential. And, there's lots of alternatives to look at (element through the boom, on top of the boom, connected or not, spacer or not, etc.)

One thing I always like doing is shopping for pet food with the wife,
and especially reading the labels ...

"Animal Digest" is a nice term on some of the cans and packages, and
basically translates into, "Stomach, intestines and anus -- AND THEIR
CONTENTS, all are included for your pets personal enjoyment!"

I just quietly put back the container, and quickly look around to see if
anyone has seen me touch it ...

ok, i'm afraid i'm going to have to ask the simple question... if you
blackbox the load and stub and look at just the one connection to it
and that gives you no reflected power... where do you define the

second port, and why?

Logic, immediately, suggests to me, that varying the frequency and measuring voltage, amperage, and SWR would begin to immediately point the answer(s.)

The current is maximum at the center, not the voltage.
>
> With a metallic boom and with the parasitic elements fastened
> to the metal would the oscillation pattern be changed?

At HF the effect is normally minimal depending on the mounting method used. Using insulated through the boom mounting it starts to be noticeable at 2m and by 70cm it definitely needs to be compensated for. 1 and 1/4 inch booms using Delrin through the boom mounts at 432 need about 7mm added.

The previous statements assume you don't use insanely large booms and mounting pieces.

Dead right.

This seems to be one reason why yagis at HF tend to be grounded elements and at VHF and up tend to be insulated. At HF it's fairly easy to get a low resistance with fairly low impedance change over a few years. That's harder to do at VHF especially with through the boom uninsulated. Hence through-the-boom or over-the-boom insulated at 2m and up.

I've built many 6m beams with no correction added and using simple homebrew U clamps. I have seen little discernible difference in their performance from predicted. Of course I shouldn't except perhaps in the side nulls. And they seemed about right. One small confirmation was the SWR curve also matched predicted.

Anyway, the problem with connected is corrosion. Can only slow it down.

> and that gives you no reflected power... where do you define the
> second port, and why?

For the two-port analysis, only the impedance discontinuity at point
'x' is in the black box. One port is the source side of the impedance
discontinuity. The second port is the load side of the impedance
discontinuity. It allows the standard s-parameters to be measured and
the standard s-parameter equations to be used.

On the source side of the impedance discontinuity:

b1 = s11(a1) + s12(a2)

On the load side of the impedance discontinuity:

b2 = s21(a1) + s22(a2)

Those are the normalized voltage equations. Squaring those equations
shows what happens to the component powers including interference
components. Reference:

IMO, the resistor load simplifies things as a single-port analysis can be used on a resistor because there is only one component of power accepted by the resistor. What would complicate things, IMO, is a 50 ohm antenna feedpoint impedance which is a virtual impedance. Analyzing the antenna as a multiple port device shows where the multiple energy components go which is a complication of the present point I am trying to make about the Z0-match point 'x'.

However, the single-port vs dual-port analysis differences at the impedance discontinuity 'x' also apply to the analysis at the load resistor vs an antenna AND at the source where Walt seems to be using a single-port analysis involving a virtual source impedance which depends for its very existence upon forward and reflected energy components flowing in opposite directions at the source impedance point which necessarily causes interference accompanied by a redistribution, not a reflection, of energy components.

Based on a fair number of simulations over the years, I'd say that SWR curves are not very sensitive to pattern degradation (except in an egregious case)..

Consider a 5 element medium gain Yagi where the currents are all roughly equal (which is what you'd have with moderate superdirectivity) and it has a F/B ratio of, say, 20dB.

Screw up the current in one of the elements by, say, 25% (so the overall excitation is now off by 5%).. That's enough to turn your -20dB null into a -10dB null (in round numbers..)

But, would you even see that in a VSWR.. say it was 1.2:1 before (reflection coefficient = 0.09).. and now the reflection coefficient changes by 5%.. so it's 0.0945.. That's a VSWR of 1.208.. I think you'd have a hard time measuring that..

I thought you might enjoy that Cecil ... I know you were really worried that RF would be failing us soon, due to a lack of suitable media ... ROFLOL!

I am sure you noticed these "jewels in the article:"

"The limit means that more virtual photons exist outside the mirrors than between them, creating a force that pushes the plates together. This 'Casimir force' is strong enough at short distances for scientists to physically measure it." -- From the article, itself.

"David - Dr. Wilson's article (ref. 1 for the article) is the source of my statement that linear acceleration cannot produce "this effect". It seems that "this effect" is the dynamical Casimir effect. The Unruh effect is something different (but definitely related). In any case, I thank you for your clarification." -- From a post, further down.

Things are happening ... finally the squeeky wheel gets some much needed maintenance ...

But cecil, with a 50 ohm NON-inductive load (not inductive over all freqs of concern), fed by 50 ohm line, from a 50 ohm source ... would find a stub a bit of a problem ... indeed, a shorted stub more so -- choice of proper line length and placement of the stub would allow its' use, on very limited frequencies, with excellent dummy load results, but the need, ever, escapes me!

Anyway, I just commented to piss old dave off ... :-) I admit it!

but what is your second source? you can always represent the second
source in that case in terms of the transmitter output so the second
input can be eliminated giving you a single port model.

[nothing, really ...]

Seems even Einstein removed it from the realm of "ponderable media", and
you have known all along, what it is ... enlighten the rest of us, and
we can see the revelation you have had!

And, let me see, ether vs. quantum sized particles? Any relationship?
NAAAA! ROFLOL!

It is like Einstein was never understood in the first place. It is like
this is the first time these people have been exposed to what he said,
like they will need time to digest all this ... simply amazing ...
correct me if I am mistaken, but the ether defines our very matter and
describes the laws which that matter must obey, right? The ether is the
rod and measure, right? If a universal clock and time frame exists, it
exists only within the ether, right?

If you don't say yes to all the above, I can only think you a kook, or
unable to understand what has been written and, generally, accepted ...
of course, it is being questioned, as it should be ...

"He went on to add ï¿½Weï¿½re in a very special moment of history, because
we are like fish who finally realized we were living in water."
http://thedartmouth.com/2010/05/07/news/space

All I know is the ether is a media, it is invisible to us, its'
properties can only be "deduced" (or, guessed at), or seen though its'
action/effects on "our matter. Yet, you can now tell me that the ether
is NOT the subject of that article ... I'd say you either:

1) Have knowledge no other man has.

2) Have iron balls the size of bowling balls.

3) Are a moron.

I am pretty close to making up my mind ... ROFLOL!

If the ether is ever denied, it will be because some idiot, such as
yourself, will step up and say, once it is fully "discovered", "THAT
ISN'T IT! BECAUSE OF _BLANK_ ." And, attempt to ignore that Einstein,
and very PURPOSEFULLY, left a place marker for the gravitational ether,
in removing it from the realm of ponderable matter ... so, whatever IS
the media which carries light and RF, whatever the media is which
establishes the speed limit on light, whatever media is the UTF
(universal time frame), whatever media composes "spacetime", "quantum

foam", that IS the ether ...

What the hell are you looking for, easter eggs? Or, just some
half-baked ego-centered way to deny ether? Really, I can't even see the
purpose, just the insanity!

You are correct. I have also measured gain and F/B and side patterns.
And they match predicted quite well.

One design was a 7.5 wavelength 432 EME antenna which had nice ground
noise performance in real world use. Which is very pattern sensitive.

Faraday's aether was made of ions and electrons (like copper). Todays space
is made of rare plasma and dust. The most of old-time physicists need the
exotic aether to explain the light polarization. For Faraday the rare plasma
and its vibrations are enough to explain all phenomena.

p.s. if the separation between the two ports is just the discontinuity
connection 'point' then the voltages must be the same and the currents
are exact opposites only because of the direction convention defined,
there can be no difference measuring on one side of a point to the
other.

a1 is the normalized forward voltage on the 50 ohm feedline from the source. a2 is the normalized reflected voltage on the 291.4 ohm feedline from the load. Those are the two sources associated with the impedance discontinuity inside the black box. a2 could just as easily be from a second generator instead of a reflection.

When the single-port model is used, if the impedance is not an impedor, i.e. if the impedance is virtual, the reflection coefficients are virtual reflection coefficients that do not reflect anything and do not absorb power. I will repeat an earlier assertion:

Since a virtual impedance is result of the superposition of a forward wave and a reflected wave, a virtual impedance cannot re-reflect the reflected wave, i.e. one cannot re-reflect the reflected wave while at the same time the reflected wave is being used to generate an impedance. It has to be one or the other. Otherwise, there is a violation of the conservation of energy principle. RF EM ExH energy cannot be used simultaneously to generate a virtual impedance while at the same time being re-reflected.

If the reflected wave is re-reflected, it must be by an impedance other than the virtual impedance generated by the reflected wave itself. If the reflected wave is being used to generate a virtual impedance, it cannot at the same time be being re-reflected.

The total voltage and total current on both sides of the impedance discontinuity must be equal. But the superposition components do not have to be equal and, in fact, cannot be equal. In the case of the Z0-matched example, the forward voltage on the 50 ohm side is 70.7 volts while the forward voltage on the 291.4 ohm side is 241.4 volts. In order for the total voltage to be the same, the reflected voltage on the 291.4 ohm side, which is 170.7 volts, must be subtracted from the 241.4 volts of forward voltage to yield a total of 70.7 volts. For the Z0-matched example:

Vfwd1 = Vfwd2 - Vref2

70.7v = 241.4v - 170.7v

Please note that the Z0-match point is at a voltage minimum on the
291.4 ohm feedline. 1/4WL toward the load, the total voltage is
241.4+170.7=412.1 volts (in a lossless system).

> Do you actually see any relation between quanta and aether theory?

Looks like you assumed I was making an exclusive assertion when it was actually inclusive. What I was saying is that all the people on the opposite side of the argument from the existence of an aether, i.e. the people who argued that a perfect vacuum is absolute nothingness, have been proved wrong. There is indeed a structure inside a perfect vacuum and "quantum aether" is just as good a name for that structure as any other words. I suggest we convert from "luminiferous aether" to "quantum aether" and be done with it.

Note that EM waves cannot propagate through absolute nothingness. That's why light cannot escape the boundaries of the universe.

In fact, I would assert that today, VSWR measurements are almost useless
for *antenna adjustment and construction*.. and even for adjusting
elements. With modern modeling codes which don't require all sorts of
little fiddly "correction factors" (e.g. taper or boom factors) to

allow simulating a complex structure with a simpler model, a tape measure would be a better tool.

There's a lot of literature from the 50s-70s and even 80s where antennas are constructed and you adjust the element length by using the trusty GDO. (Yep, I remember helping my grandfather assemble a multiband Yagi of some sort in the early 70s doing it that way..)

But today.. mechanical dimensions and a high fidelity model are the way to go.

Where the VSWR measurement would be useful is in two places:
1) Adjusting a wire antenna length... they're usually interacting with the surroundings, so you have to cut and try, and a VSWR sweep is a good way to get there quickly. Putting up that triband multiwire dipole for Field day tomorrow? The Antenna analyzer is your friend when trying to get all those mutually interacting lengths dialed in.

2) A quick check to see if an antenna system that worked before has "broken" in a big way.

1610. 20m FD Dipole

Newsgroup: rec.radio.amateur.antenna

I've participated in Field Day every year since 1993, when I was first licensed. Because I had a big 2m beam, I worked that band aggressively, sometimes making the most QSOs. Unfortunately we lost our hilltop FD site in 2009 and the 2m production "down low" was disappointing in '09 and '10.

This year some youngsters want to work 2m, so I'm moving to HF, 20m being the most promising, I think. With the help of EZNEC (evaluation version), I modeled a promising 20m dipole at 30'. It's almost exactly 75 ohms resistive at the freqs I want to use and I'm going to feed it with RG-6, 0.7 dB/100 feet. My radio has an internal tuner to match the 75-ohm cable, if I need it.

I'll report the results.

I disagree. There are 100W supplied by the source and 100W consumed by
the load. There are 200W in the 291.4 ohm line. 100W of that is just
"passing through". The other 100W is circulating, that is, stored energy
which was put there by the start-up transient. If it is circulating,
then it must be reflected from each end of the 291.4 ohm line.

Cheers,
John

Let's assume that the 100 watts is just "passing through". It would change from 70.7 volts in the 50 ohm environment to 170.7 volts in the 291.4 ohm environment. The reflected power is 100 watts so the reflected voltage is also 170.7 volts. Those two voltages would have to add together to get the forward voltage. The forward voltage is known to be 241.4 volts. Exactly how do you add two 170.7 volt in-phase waves to get a total of 241.4 volts?

Here is actually what happens. Since the physical power reflection coefficient at the Z0-match point is 0.5, only 50 watts of the source power makes it through the impedance discontinuity. That voltage is 120.7 volts. The same thing applies to the reflected power - only 50 watts is re-reflected by the 0.5 power reflection coefficient. So the re-reflected voltage is also 120.7 volts. Adding those two voltages together yields 241.4 volts which we know is the correct forward voltage.

Now you are going to ask how two 50 watt waves can add up to 200 watts forward power. That's just the nature of constructive interference since power is proportional to voltage squared. If we add two 50 watt waves in phase, we get a 200 watt wave. Where did the extra 100 watts come from? Why, from the 100 watts of destructive interference toward the source that eliminated the reflections toward the source.

try it! you will read the exact same voltage on either side of that
connection point!

wow, it takes eznec to model a dipole for field day now? not that
many years ago i ran a competition at field day... given a hunk of
coax(with one connector installed), a roll of wire, and some random
pieces of rope, cut a 10m dipole, get it up in the air, and make a
contact. no eznec, a tape measure if you really wanted it, and who
knows what the coax was.

Hello Michael,

Owen's reference explains everything in detail.

If you want a very short answer:
The two-core balun has common mode suppression characteristics. That means when your balanced load isn't balanced in real world, the balun will reduce common mode current in both coaxial line as well as balanced line.

The single-core balun is electrically more like an autotransformer with the coaxial ground on the center-tap. This arrangement does not provide any common mode suppression. So only in case of a perfect balanced load, everything will be fine (with the single-core balun).

Now the longer part
If you still want to go for the single-core solution, you may add a separate common mode choke. For common mode behaviour, the two cores in the two-core balun are in parallel. So the effective common mode impedance will be half that of the CM impedance of a single core.

Regarding the number of turns for the balun; when you need 8 turns on each core for the two-core solution, you can use 4 turns for each branch in case of a single core solution. So if you make the single core balun with coaxial cable, you will have 8 turns of coaxial cable around the core.

Slightly off-topic.
Be aware of the fact the actual input or output voltage determines the heat loss in the ferrite cores. So if the VSWR at the balun is very bad, and the balun is in the voltage maximum, core loss may increase significantly.

With kind regards,

Wim

> try it! you will read the exact same voltage on either side of that
> connection point!

I already told you that only applies to the total voltage and total current. You will NOT read the same forward voltage on either side, you will NOT read the same forward current on either side, you will NOT read the same reflected voltage on either side, and you will NOT read the same reflected current on either side. The total voltage and total current are the results of the superposition of the four component voltages and currents that obey the rules of wave reflection mechanics. Recognizing the interference patterns when two phasor voltages are superposed is the key to understanding exactly what is happening to the energy in the waves. At an impedance discontinuity in a transmission line some distance from any active source, the average destructive interference power in one direction MUST equal the average constructive interference power in the opposite direction in order to avoid a violation of the conservation of energy principle.

So why isn't the forward current flowing into the impedance discontinuity equal to the forward current flowing out of the impedance discontinuity? The answer to that question will solve Walt's apparent contradiction between voltages and powers. Look at the Z0-match again.

source--50 ohm--+--1/2WL Z0>50 ohm--50 ohm load

The total current on the 50 ohm side of point '+' is equal to the total current on the Z0>50 ohm side but the current on the 50 ohm side is a flat traveling wave *constant* current while the current on the Z0>50 ohm side is a standing-wave current maximum, i.e. the total current on the Z0>50 ohm side is a *variable* that changes with a change in the measurement point. A variable current is NOT the same as a constant current.

The total voltage on the 50 ohm side is a flat traveling wave *constant* voltage while the voltage on the Z0>50 ohm side is a standing wave voltage minimum, i.e. the total voltage on the Z0>50 ohm side is a *variable* that changes with a change in the measurement point.

The power on the 50 ohm side is V*I where V and I are constant values. The power on the Z0>50 ohm side is V*I*cos(A) where A is the angle between the current phasor and the voltage phasor and, because of the standing waves, all three parameters vary with location on the feedline.

If the reflections toward the source is eliminated, how is it that it

You answered your own question - if reflections toward the source are
eliminated in a Z0=50 ohm environment, the apparent (virtual)
impedance cannot be anything except 50 ohms. When you look at yourself
in the mirror, your reflected apparent (virtual) distance behind the
mirror is the same as your actual distance from the mirror. The
reflection is NOT where it appears to be, i.e. it is virtual.

You said "Since a virtual impedance is result of the superposition of a
forward
wave and a reflected wave, a virtual impedance cannot re-reflect the
reflected wave, i.e. one cannot re-reflect the reflected wave while at
the same time the reflected wave is being used to generate an
impedance."

But, it does. First, it causes the 50 ohms line (looking into the 291.4
ohms line to see a match due to the reflection. Second, the
re-reflection from that discontinuity is half of what maintains the
circulating energy on the line. The other half is the discontinuity of
the non-virtual load.

That sounds fine as far as it goes.

You might consider a 1:1 current balun, a W2DU style one should suit this application fine.

I applaud your efforts to understand the thing using a modelling tool. To some of us, the inquiring mind and the interest in the technology of radio communications is what ham radio is really about. For those not so interested there are contests!

Your model though contains a guess for ground parameters, and possibly other site effects not included. You must expect some variation from model, but those variations would not cause very high VSWR on the line, line losses should be quite acceptable, and an ATU should transform the load it sees to that required for rated output from the transmitter with quite acceptable losses.

In my experience, antennas less dependent on ground are more likely to give consistent performance for field operations where you usually cannot afford to be installing significant ground systems.

Well done OM.

Owen

when someone gives me a voltmeter i can touch to that connection point
and measure the 4 components then we can talk. as far as designing
anything i need i can do it without giving those s parameters or your
4 components a second thought. it is very easy to transform and
combine the impedances to tell me what the load seen by the
transmitter is, or to figure out the needed stub for providing a
proper match without all that stuff.

And we get that higher education in a netnews group? I enjoy this group, but it's the equivalent to getting marriage advice at a bar. Maybe good, but just as likely really bad.

Yeah, kinda, but that's all right. I already have four working dipoles up at home, each produced much as Dave describes; 40, 20, 20, 10.

I was seeking optimization and I got it. Example: My TS-870 electronic display lights up five little dots for a 1.5:1 SWR. As installed, the new antenna gave me only three little dots -- most of it probably right at the back of the radio in the transition to 75 ohms. I am very, very pleased with the results.

20m was lit up like a Christmas tree all day and into the night. While operating 100W, I logged a new QSO every two to five minutes. (I'm nobody's idea of a contester.) Surprise -- broke a few pileups.

I oriented the antenna for max toward 060 degrees True, the bulk of North America from San Diego. Putting up three guyed 30-foot poles was quite the adventure but it all worked. No blood loss, one blister. :-)

"Sal"

PS: TS-870 reported an untuned 3:1 SWR on 15m, which the tuner handled easily. Many QSOs on 15m.

The fun part of antenna modeling, at least for me, is seeing how close the real thing meets the design. We put up an antenna for FD, an 80 meter cut for the cw portion of the band, and hit it on the first try.

As for folks tuning up rain gutters and wire salvaged from an old toaster, then making an antenna out of it, that's fun too, but the final result isn't likely to be optimum.

I use EZNEC 5 nearly every day. It saves me time & money. I can minimize my physical work as well. At 71 years old that is getting more important every day. Last week I took down my Fan of dipoles and put up a 40m half wave in series with an 80 meter half wave, fed at 33% from one end. The wire was handy and so was the room. What a waste and in 90 degree + weather too. If I had modelled it first, I would have done it. Hard to feed everywhere and the low activity seem to endorse the computed patterns.

I ran an inverted Vee through EZ5 with 43 foot wires on each side and it looked as good as anything on 40 & 80M and was easy to tune about anywhere. The testing has supported that the 30M and up patterns are not nearly as useful as the corresponding dipoles, but it does work everywhere. I got the 43 foot wires by simply folding the excess from an 80M dipole and taping them. Nothing permanent, no $ spent. I will likely keep this for 40 & 80. Probably back to adding in a couple of dipoles for 30 & 17 in a fan configuration while I consider my first venture into my first Quad effort.

20-15-10 are covered with an A3S Cushcraft at 60 feet. I don't understand it, but it works good.

1641. 43 foot verticals

From: Wayne <mygarbagecan@verizon.net>
Message-ID: <iubabfpnk1@dont-email.me>
Source record: 4442

I have seen two commercial antennas advertised that are each 43 feet tall,
and have no traps/stubs, etc.
There appears to be a 4:1 balun at the feedpoint. Mentioned, is the
requirement to have a tuner at the driving end of the feedline, and max
VSWRs in the 4:1 range.

Playing around a bit with EZNEC, the feedpoint impedances over the
operating range have some large swings. Can anyone shed light on how
effective the antenna should be?

That is a disease that affects, as a SWAG, about 80% of the core
population here.

Then there are the people that ask questions because they are trying to
actually build something. Who almost always get what is effectively
GobbldeeGook in response.

All they just want to know how to make something that is "OK, works good
enough" and they have to wade through dozens of useless responses to
maybe get one that's worthwhile.

Welcome to rraa, where no one "important" ever agrees.

Hi Wayne,

Actually, it depends more on the ground, or its proximity. If you can
get all the energy into the antenna (hence the tuner and BalUn), then
it leaves (the whole point of our hobby). If you have very few
radials and you are close to ground, when that energy leaves, a lot of
it is absorbed into the ground (not very productive).

Now, the height of this radiator can be something of bad thing for the
higher bands. 10M will become deaf because most of the energy is
oriented high into the sky, and deep into the ground. True, you
"could" force a decent match, but that is only half the story of
antennas. The same is probably true for 11M, 12M, down to a fairly
good match and operational application for 20M and below to, maybe,
60M.

EZNEC should bear out instructive numbers and graphics to all these
observations.

One curiosity about this - the 4:1 BalUns. This sounds like a Hail
Mary throw - a sop for the sucker. Do you count yourself among that
select population? Why? Because technically they would be UnUns.
Further, it is strange to think that a transformation ratio of 4:1 is
applicable anywhere, much less everywhere.

Hi Michael,

Looks like the author went to a lot of trouble - with passion.

There is nothing unreasonable about the design or the results.
However, you should note these designs are highly removed from
ground's proximity which can skew many, finely tuned projects.

You should also note what is typically referred to as the decline on
return for your investment as the design gets bigger. Further, in
actual construction, you rarely obtain the mathematical precision that
is required to enjoy the forecasted results.

Hi Wayne,

Actually, it depends more on the ground, or its proximity. If you can
get all the energy into the antenna (hence the tuner and BalUn), then
it leaves (the whole point of our hobby). If you have very few
radials and you are close to ground, when that energy leaves, a lot of
it is absorbed into the ground (not very productive).

Now, the height of this radiator can be something of bad thing for the
higher bands. 10M will become deaf because most of the energy is
oriented high into the sky, and deep into the ground. True, you
"could" force a decent match, but that is only half the story of
antennas. The same is probably true for 11M, 12M, down to a fairly
good match and operational application for 20M and below to, maybe,
60M.

EZNEC should bear out instructive numbers and graphics to all these
observations.

One curiosity about this - the 4:1 BalUns. This sounds like a Hail
Mary throw - a sop for the sucker. Do you count yourself among that
select population? Why? Because technically they would be UnUns.
Further, it is strange to think that a transformation ratio of 4:1 is
applicable anywhere, much less everywhere.

73's
Richard Clark, KB7QHC
****
Thanks for the comments Richard. Indeed, the EZNEC model that I looked even

created a question of which direction was best for a 4:1 "balun". That would require more examination of the data than I have yet done.

My interest would be in a half sized version of the antenna (or less) for 20m and above. I have a pretty good ground available in the form of a metal patio cover. The no-brainer approach is to use full sized 1/4 wave radiators for various bands. But a simple way of tuning a single radiator for multiple bands is more appealing, since band changes are much simpler.

Very real. I built the 2.4Ghz version. It works, but is rather
large. Unless you have plenty of real estate and tall towers, this is
not an HF antenna.

His curtain quad calculations and NEC2 deck are at:
<http://home.comcast.net/~ross_anderson/CurtainQuadFigure11.htm>

There's also the Sterba Curtain
<http://imageevent.com/holl_ands/notfortv/sterba;jsessionid=ldhsj5x2v1.penguin_s>
Gray-Hoverman
<http://imageevent.com/holl_ands/grayhoverman/hovermantype1>
and other antennas
<http://imageevent.com/holl_ands/chireix/chireixmesnyrefl>
resembling a collection of quads. As long as you get the phasing
correct, almost any geometry will radiate and have gain.

>
> One curiosity about this - the 4:1 BalUns.

As with many of these "matching devices at the base of a vertical" they're not actually a broadband 4:1 ideal transformer. they tend to have a fair amount of leakage inductance and capacitance, and (by empiricism) they have a design which generally improves the match over a wide band. At low frequencies, where the feedpoint Z is low, the shunting effect of the interwinding C isn't as big, so it acts more like a transformer. At higher frequencies where the feedpoint Z is higher, the interwinding C tends to "bypass" the transformer, so it works less like a transformer, and you see more of the Z of the antenna.

You can fool around with some test data and a lumped model (with lots of parasitics) and come up with some numbers for the parasitics that works out pretty well and combined with some loss in the feedline, makes the typical match at the transmitter end not too bad (within the range of a tuner that can handle, say, 2.5:1 or 3:1, mostly reactive)

It is almost impossible to *design* such a thing from that data. I am quite certain that these things were designed by empiricism. Spreading the windings or squishing them, choosing various winding ratios, etc. until it works "good enough".

The underlying problem is, as you pointed out, that a 43 foot radiator on higher bands has a pattern that is somewhat less than ideal.

A trapped vertical might be a better solution, although mechanically a bit more complex and definitely more "antenna looking"..

There are some very clever lumped networks which will tune multiple bands with a single radiator. They're a lot more complex than a simple L and C, (in general, at least one L and one C per band), and they're not designable by simple paper and pencil techniques (so they don't show up in QST articles or in the handbooks), but with a computer to help, it can be done.

Over a 2:1 frequency range, the pattern issues aren't as big a deal too.. You could pick a radiator that's sort of in between.. it's a bit long for 10m and a bit short for 20m.

Hi Wayne,

The Hail Mary I spoke of also includes:
>>requirement to have a tuner at the driving end of the feedline
Kind of a belt and suspenders solution which in the long run makes
this purchase an expensive option to simply buying staged tubing. In
that respect, the only value added could be a decent mount....

>My interest would be in a half sized version of the antenna (or less) for
>20m and above.

Hmmm, sounds like you are a prospect for my suggestion of staged
tubing.

>I have a pretty good ground available in the form of a metal
>patio cover.

And I would presume this to mean an elevated vertical design - good.

>The no-brainer approach is to use full sized 1/4 wave
>radiators for various bands.

There's no obvious advantage there when you have to use a tuner
anyway. They would be helpful in taming the mismatch, so go ahead.

>But a simple way of tuning a single radiator
>for multiple bands is more appealing, since band changes are much simpler.

Look into the topic of "folded monopoles."

I bet it radiates equally poorly in all directions.

Democrats view George Orwell's novel "1984" as a cautionary tale.

Republicans see the novel as their blueprint.

Hi Richard,

I note that these were designed at 1296. They would likely be a
practical antenna on that band and ground would not be an issue although
trees may be.

I wonder how hard it would be to make one as a printed circuit board?

Not too long do I wonder. The structure will be exactly as defined
within limits of the board specs.

The only issue is how large PCB stock I can buy.

Hi Tom,

If you could generate a graphic with controlled geometry at that
scale, and then etch it, yes, I think it would work quite well.

I will now (most modestly) add my own contributions posted some
decade++ ago (humble, humble) at:
http://www.qsl.net/kb7qhc/antenna/fractal/pg244c/index.htm
for which we may thank the ex-N1IR (who graciously abandoned his
soiled moniker for another to inherit) for the fractal variant to
orthodoxy. Oh woe betides the unknowing innocent for whom this may
all seem irreverent and confusingly impenetrable. (Yes, I am in my
cups. Taking a bow. Grandiloquent sweeping gesture to the audience.)

Moses says,
"Love for The Divine did not register quickly in many minds, but at the Birth of The Son of The Creator, mankind became aware of a Higher Being, the True Existence that there was a Divine. At this time in which you live, there are numerous evidences that many, many, many, many men, women and children do not recognize the True Existence of a Creator and All that surrounds The Creator as Ultimate in Purpose, Cause, Reason and Reality."

REVELATION DELIVERED THROUGH FRANCES M. KLUG ON JANUARY 27,2000 AT 2:30 P.M.

MOSES

"I am Moses. Throughout time, human life has been fully aware of the importance of a moral code of ethics versus an immoral code of ethics. In the beginning of Christianity, The Son of The Father stood upon the earth in the human form, as Example, as Direction, as Hope, so that others would learn about the importance of human actions and human abilities, plus human dignities that were perhaps not just normal, but necessary.

Love for The Divine did not register quickly in many minds, but at the Birth of The Son of The Creator, mankind became aware of a Higher Being, the True Existence that there was a Divine. At this time in which you live, there are numerous evidences that many, many, many, many men, women and children do not recognize the True Existence of a Creator and All that surrounds The Creator as Ultimate in Purpose, Cause, Reason and Reality.

As We Saints try in many ways to enlighten mankind of the importance of purity in the mind, in the body, because of the Soul each one is the custodian of, We find that indifference, based on demonic measures, is always evident, because the enemy causes interference that, to individuals, give excuses to not abide by the Commandments of The Creator.

As The Father down through time, since the beginning of time, has used human life, human lives, to be Example, to be Instructors, and to act morally sound, The Father at this time has given to mankind an additional Gift of Divine Love, Words of Direction that cannot be dismissed as normal or personal to the individual through which They come. I assure you It is strictly Guided, Guarded and Delivered by The Divine, just as it was at another time.

The Gift of life is a Gift not always seen for the greatness it is, but there is hope in it, there are Rules that guide it, and there is definitely a Divine Love instilled in it that no other living matter or thing has.

As I speak to you today, I beseech you, look at what is pure, logical, understandable, and has a Goal to it, and resist what is obviously more pleasing to what would be impure, unkind, unjust, totally different than what you can visualize The Kingdom of God to be. So be it."

You are confusing reflection with wave cancellation (destructive interference). I suggest that you study the separate sections on reflections vs interference in "Optics", by Hecht. Nowhere does any optical textbook indicate that superposition and reflection are the same thing (and they are indeed NOT the same thing).

Superposition/interference applies to two or more waves. Reflection applies to a single wave. When a reflected wave is re-reflected, it is always a single wave event. Take a look at one of the s-parameter equations:

b1 = s11(a1) + s12(a2) = 0

b1 is the reflected voltage toward the source which is, of course, zero when looking into a Z0-match.

s11(a1) is the forward source wave reflected from the physical impedance discontinuity at the Z0-match point. Note: This is a single reflected component of a single forward wave.

s12(a2) is the part of the reflected wave from the load that is transmitted back through the impedance discontinuity at the Z0-match point. Note: This is a single transmitted component of a single reflected wave.

Reflections are now over and done with. What happens next is superposition/interference, i.e. the phasor addition of the two component reflections. Note: The results of the phasor addition of two component waves is NOT a reflection!!!

The zero result of the addition of those two phasors is associated with destructive interference toward the load. That's what causes the 50 ohm Z0-match, not the component reflections. The redistribution of the destructive interference energy back toward the load is NOT a re-reflection and here's why:

A re-reflection preserves the modulation content of the re-reflected wave which can be proved by TV ghosting experiments. Wave cancellation due to destructive interference does NOT preserve the modulation. In fact, any differences in modulation between the two superposed wave

components would wind up incident upon the source.

I could design an expensive device that will do exactly that but it is
a lot easier to just calculate the values using Mathcad.

Yes!

I know I've told this story here before, but ...

My first HF antenna was a 10m vertical sleeve dipole. It was mounted
only a few feet above ground. With a tuner,
I matched 15m but not 20m. I knew I needed more metal on at least one
element, so I grabbed a clip lead and a hunk of wire and headed
outside. Near the antenna, I almost tripped over an extension ladder
laying on the ground. This is a sign, I thought. I tossed the wire
and dragged the ladder over to the dipole and clipped it onto the
lower element.

Back inside, I tuned up nicely on 20m and answered a CQ. Had a nice
chat with a fellow in Hawaii; five-by copy both ways.

Some wag in this group suggested "ladder line" might improve the
setup. Good one.

True, but that ignores what is for me the essence of our hobby,
namely,
"Let's try this and see what happens." We're looking for betterment.

Sometime we make smoke (Me, twice, so far.)
Sometime we make a pleasing discovery. (Me, too many times to count.)

I will not be changing to the " ... throw a piece of wire ..." school
of thought,
as my organized (or maybe semi-organized :-) experimental process is
more enjoyable.

I should add I spend more time in QSO than I do playing with the
theory.

Thanks. I did have the current balun but failed to mention it. I had
25 Mix 43 beads, Coil Winding Specialist P/N SB-6873-43. I see now
(my after-the-fact research) that Mix 73 would have been more
effective at 20m. ("We get too soon old and too late smart.")

I have baluns on all my dipoles, two voltage baluns and two eight-turn
coax cable wound baluns on my home station and a spare eight-turn
balun in my travel box.

I have read that the W2DU balun should be repeated at intervals along
the feedline, some wavelength fraction, but I found no confirmation in
ten minutes of searching. Got anything on that?

Hi John,

Perhaps I might answer by nominating some that are more dependent on ground.

The classic case would be a monopole worked against real ground, meaning having one terminal of the feed line connected to the dirt in some way.

A centre fed dipole rigged very low to real ground is more depended on ground than one that is higher.

My experience is that if you don't have the time or resources to install a substantial ground system, avoid antennas that depend greatly on that ground system for performance. Driving a short conductive stake, or running a wire along the surface, or running a wire into a body of water does not make an effective ground system for these purposes.

I recently had QSO with a field station on 40m at about 500km distance. Initially he had a half wave dipole lying on the ground, and was somewhat surprised that I could work him with 100W from his tx. He raised the dipole to 5m (15') and we tried 50mW SSB. He reported that I was essentially noise free at that, but I could not reduce power any further.

We prove time and time again that anything "works", but an antenna less dependent on the ground usually gives more consistent performance.

I think i have finally seen the confusion point. you can not at the same time talk about reflected waves and re-reflected waves and also use s parameters or other steady state reflection parameters or impedances... this means you can not talk about individual reflections from the stub connection point without also analyzing the traveling wave inside the stub, nor can you track and sum up all the reflections using the steady state impedance of the stub as if it were a lumped value. to do so violates the conditions where the s parameters and reflection coefficients are valid, the sinusoidal steady state realm.

John, EM wave reflection is what happens to a single wave. EM wave superposition/interference is what happens between two (or more) waves. They are not the same phenomenon and do NOT obey the same rules of physics. Wave cancellation between two waves is *NOT a reflection* but it does *redistribute* reflected energy back toward the load at the Z0-match point. The destructive interference energy toward the source is redistributed as constructive interference energy toward the load but one can tell from the resulting phase and magnitude that it was NOT a reflection.

A good reference on the differences between wave reflection and wave superposition/interference is "Optics", by Eugene Hecht. The international 4th edition is available in paperback for around $20 from Abebooks.com.

1682. YAGICAD question

Newsgroup: rec.radio.amateur.antenna
Date: 2011-06-30 18:15:34 UTC
From: "Helmut Wabnig"
Message-ID: <k5dp075i2mlhjcn30su4rdkli9re0lcft5@4ax.com>
Source record: 4383

Am trying to design a 3 element tape measure antenna for 2 meters
with a 10x10 mm aluminium boom. After calculating the dimensions
with Yagicad 6.1 the tapes get cut and mounted.

http://img837.imageshack.us/img837/8209/snc14096a.jpg
(Before cable and hairpin match)

The driven element sits on a slider which allows to adjust
for best F/B ratio over the working frequency span of the antenna.
Normally the F/B degrades quickly when tuning off center.

http://img90.imageshack.us/img90/7112/fbratio.jpg

With the driven element on a slider you can move the peak
to the desired frequency, within a certain range.
About 10 MHz span is possible with such a 2 meter antenna

Measuring with a scalar analyzer and tests with actual radio signals
reveal that YAGICAD does calculate too short elements.
Everything is a few MHz too high in frequency, the gain maximum,
the F/B optimum, the resonant frequency, on the antenna,
when built with the YAGICAD dimensions.

The only parameter I can vary in YAGICAD is the element diameter.
The tape measure is iron, 19 mm. Iron can be selected
in YAGICAD, but that only affects little.

I optimize the design for best F/B ratio, because that is what you
want for a direction finding antenna.

I have to add 4 cm to the passive elements and 8 cm to the driven
dipole to get a working antenna, having selected 0,02 m element
diameter in the YAGICAD program. Entering less diameter
worsens the situation.
The boom adds only 1 or 2 mm to the elements, but the final
dimension results are several centimeters off!
The SWR is excellent with the hairpin calculated by YAGICAD.
At least something that works.

Luckily I have a good test equipment and see live on the screen
what the antenna does when I change elements.
But that YAGICAD is a mysterium to me.
After so many revisions I would expect some more realistic results.

> VSWRs in the 4:1 range.

Several manufacturers supplied and recommended a 4:1 voltage balun at the feed point of their 43' unloaded vertical. It would seem driven by one seller, and a mob of sheep following.

If you look on eHam at the evaluations of the configuration, you will find that most reviewers thought it a great antenna system.

I commented on that in some web articles and many postings in online forums over years. My thoughts in seeking an understanding of how it "works" are in the article at http://www.vk1od.net/balun/application/Z5.html .

I should note that after a particularly vigorous discussion in one forum a year of two back, one of the sellers changed his recommendation to an unun and advised existing owners how to modify their balun to an unun. The method was quite the same as I previously documented at http://vk1od.net/antenna/multibandunloadedvertical/ .

The whole saga reminds us that anything "works", and flexible sellers remain poised to supply to the current fashion.

I sort of expect they will get it straightened out before
too long. I think they are doing some massive changes. The
search engine, groups, the whole mess..
Supposably July 1 is when the new system is supposed to
be kicked in. Whether GG will be right by then, who knows..
I'm using eternal-september.org right now. It's pretty
good for a free news server.
But believe it or not, I actually prefer google groups.
Some people shake their heads when I say that, but screw
em if they can't take a joke.. :/
To me, the web based reader is faster and less cumbersome
than using the regular news readers.
Fer instance, on the regular reader I have to look at each
post individually. With GG I see all posts in a thread at
once. It's faster..
Also, if I start fresh on the news server, I have to log in
with my user name and password. And then I have to type in
the new groups I want to look at.. What a pain..
Where as GG, as my usual groups are saved with my "profile"
or whatever you want to call it.
I'll think I'll keep both going, but if they get GG back
in order, I'll likely revert back to it, and keep the
eternal-september.org as a backup.

1686. Crossposting Permitted to rec.radio.amateur.moderated

URL: http://www.panix.com/~rram/usenet/rram/index.html

Changes followed by "|".

After a 30-day public discussion and feedback period to gauge reader
opinions in March of 2009:

http://groups.google.com/group/rec.radio.amateur.moderated/browse_thread/thread/d7d337db35
f23326

the rec.radio.amateur.moderated Moderation Team has decided to consider
amending its charter, and permit limited simultaneous crossposting to
rec.radio.amateur.moderated and one other unmoderated
amateur-radio-related discussion newsgroup. We are currently trying
this on a temporary basis (90 days, through early July 2009), and adopt
it permanently if successful.

Approved rec.radio.amateur.* newsgroups are those that are currently
listed in the latest version of the "List of Big Eight Newsgroups" which
is crossposted monthly to news.announce.newgroups, news.groups, and
news.lists.misc.

Approved alt.radio.amateur.* and alt.ham-radio.* newsgroups are those
that have been created consistent with the suggestions in "So You Want
to Create an Alt Newsgroup" at:

http://www.faqs.org/faqs/alt-creation-guide/

Approved regional hierarchy newsgroups are those that contain either
"radio.amateur" or "ham-radio" in their names, including
uk.radio.amateur and aus.radio.amateur.misc.

We will make every reasonable effort to keep our list of approved
newsgroups up-to-date. In case we have overlooked any, and a submission
is rejected in error as a result, the rejected submitter can E-mail us
at our administrative contact address (in the signature at the bottom of
this article, and the default Reply-To for the rejection message)
requesting that it be added, and that the article be approved. We may

That's because optical physicists seem to be the only technical people who understand interference effects. However, most of what one needs to understand about the subject is contained in my Worldradio energy article:

Someone said it a long time ago: You can't have your cake and eat it too.

One cannot be using the reflected wave to establish a dynamic virtual short while, at the same time, the virtual short is causing a dynamic re-reflection of the reflected wave.

The virtual impedance is (Vfor+Vref)/(Ifor+Iref) but if that is the impedance doing the re-reflection of that same Vref and Iref, then it cannot also be being used to establish the dynamic virtual impedance, i.e. if a virtual impedance is re-reflecting all of the reflected energy, it will necessarily disappear from existence because there is no longer a Vref and Iref to cause it to exist.

Are there any advantages and/or disadvantages to having a dipole where
the legs are at a 90-degree angle instead of straight (i.e., one leg
oriented north-south; the other east/west)?

Several manufacturers supplied and recommended a 4:1 voltage balun at the
feed point of their 43' unloaded vertical. It would seem driven by one
seller, and a mob of sheep following.

If you look on eHam at the evaluations of the configuration, you will find
that most reviewers thought it a great antenna system.

I commented on that in some web articles and many postings in online forums
over years. My thoughts in seeking an understanding of how it "works" are in
the article at http://www.vk1od.net/balun/application/Z5.html .

I should note that after a particularly vigorous discussion in one forum a
year of two back, one of the sellers changed his recommendation to an unun
and advised existing owners how to modify their balun to an unun. The method
was quite the same as I previously documented at
http://vk1od.net/antenna/multibandunloadedvertical/ .

The whole saga reminds us that anything "works", and flexible sellers remain
poised to supply to the current fashion.

Owen

Thanks for the interesting links, Owen. The 4:1 balun did look unusual to
me, and EZNEC didn't help reveal the magic involved. As I mentioned before,
I have challenging antenna restrictions (not restrictive covenants), and
will look some more at a shorter version for higher frequencies.

It is that it is a voltage balun that is the main issue. The transformation ratio is questionable, but not nearly as clear an issue as being a voltage balun between a coaxial feedline and ground mounted vertical where one terminal of each should be close to the same (~ground) potential.

There is often good argument for a current choke or current balun feeding such an antenna. If there is good argument for a 4:1 transformation ratio, then there is good argument for a 4:1 current balun. I suspect that the changed recommendation to a 4:1 unun is because that can be achieved with a simple reconfiguration of the existing component, a low cost customer support solution.

Seller's are caught between supplying product for which there is demand by the ham buyers, and one that can be explained rationally. One balun seller explained that ham buyers want 4:1 voltage baluns for multiband dipoles because when they replace them with 1:1 current baluns, they have problems with flashovers, and they can't match up on some bands. It is true that voltage baluns can facilitate matching on some extreme loads, at the expense of system efficiency, similar effect to some extent to the subject case.

NEC2 does not model conductors passing into the ground well, so you are unlikely to build a good model.

I toyed with creating a model in NEC4, but figured that those who wouldn't see the folly of the AS/Z5 balun idea would not be informed by NEC models anyway.

> before, I have challenging antenna restrictions (not restrictive
> covenants), and will look some more at a shorter version for higher
> frequencies.

Just because the 4:1 voltage balun seems irrational, that doesn't dismiss the unloaded vertical, nor benefit of a current balun.

But, if you are primarily interested in higher bands, a shorter vertical with elevated radials will likely be more efficient and less a cloud warmer pattern wise.

I am a newbie in EZNEC (eznec.com) antenna modeling, but I tried it
with a known-functional arrangement, a 20m dipole at 30 feet.

When I rotated one leg as you described, the feed point impedance came
down from 75 ohms, the resonant freq went up slightly out-of-band and
the pattern was nearly circular.

I dropped the antenna to 25 feet and the resonant freq came down into
the band and the impedance hit 50 ohms almost on the nose.

For all practical purposes, your change is close to an omni. One
issue: It has a fairly high take-off angle at 48 degrees. Some
people do not worry about take-off angle, the elevation angle of
maximum radiation. This is because the differences are only a few
dB. It takes 6 dB to make a one s-unit change, so you're not totally
ruining your chances for a QSO if you're down a few.

I've runs lots of dipoles set up like that.
Usually because of the location of the end
supports. They generally work fine, and I imagine
the model is accurate enough for gov work.
It's best not to use angles less than 90 degrees
apart though. As you get the legs closer together
like a V beam you should start to see some cancellation
and a reduction in performance. But even those will
work well enough to operate and probably beat some
lesser antennas. 90 degrees apart works just fine.
It alters the pattern, but it's still efficient
assuming it's fed properly. I always prefer coax
for single band dipoles or dipoles fed in parallel.
No matching required, and you will be hard pressed
to beat the efficiency on most any HF band using
normal line lengths.

1696. Does anyone have plans for a 4:1 air core balun that actually works?

Newsgroup: rec.radio.amateur.antenna
Date: 2011-07-02 22:10:49 UTC
From: Michael <google@shadowstorm.com>
Message-ID: <e820bd25-b016-45f3-9511-859b588fed9b@n5g2000yqh.googlegroups.com>
Source record: 4397

I've been enjoying several Lazy H antenna I built for 10 meters that are being fed with 450 ohm ladder line back to the tuner. They antennas are performing well. The problem is the external baluns I am using back at the tuner heat up even at 100 watts. These are suppose to be 1.5 kw baluns, but they can't handle the impedance mismatch for full legal limit. I have commercial 1:1 voltage baluns and 4:1 voltage baluns.
I decided to build an air core balun in hopes of saving myself the expense of buying several torrid cores. The problem is none of the plans listed in the Bill Orr handbook or that I have found on the Internet actually work. On my one commercial 4:1 balun if I place a 200 ohms resistor across the leads of the balun I get an SWR reading of about 1.1:1. When I build the air core balun listed in the William Orr handbook I get a 2.5:1 SWR.
Hmm..So I decided to try some 4:1 air core balun designs off of the Internet as well. I found the web page below;

"A 4:1 Air-wound Balun"
http://combotec.com/projects/balun14/balun14.html

I built the balun exactly like the web page described. It does not work. 2.5+ SWR on 10 meters with a 200 ohm resistor plugged up to the terminals. The same 200 ohm resistor shows close to a 1.1 on a ferrite 4:1 balun.

So, the Bill Orr 4:1 air core balun listed in his handbook does not work on 10 meters. Neither does his 1:1 air core balun when tested on 10 meters with a 50 ohm resistor. The 4:1 air core balun listed on the web page above does not work either. I'm getting tired of building air core baluns that don't work.

So....,does anyone have any plans for a 4:1 air core balun for feeding 450 ladder from a tuner that you have actually tested and used that and it shows close to a 1.1:a SWR when presented with a 200 ohm load?

By the way, of the 4 or 5 1:1 commercial baluns I purchased back in the 1990s only one of them actually shows a 1.1:SWR when presented with a 50 ohm load. The others show between a 1.7:1 and 2.1:1 SWR on 10 meters, and that is among several baluns that were all the same model from the same manufacturer. I'd post the brand name, but the paper brand labels wore off years ago. I can tell you it has little brass machined screws and brass holders on the sides of the balun and not the piece of copper wire coming out to the eye hooks. They are enclosed inside the typical white PVC pipe with caps on each end and a coax connector at the bottom.

Therein lies a possible explanation of your problems.

If you view the 4:1 voltage balun as device that can transform any load from say 5+j0 to 5000+j0 (just staying on the X=0 axis) at 1kW (for round numbers), you expected it to handle 15A, and withstand 3000Vpk, over more than a decade freqency range, and to have a maximum loss of say 20W (which is about enough to heat the core in most enclosures to Curie point) or 98% efficient.... and then give a near ideal impedance transformation.

Well, it just doesn't happen that easily... as you now know.

Hi Owen and thanks for responding,

So how do I go about feeding a Lazy H with ladder line back to the
tuner for high power without over heating the balun? The tuner is a
Dentron MT-3000a. The built in balun is not balanced at all at 10
meters, and I had to bypass it to get the Lazy H's to work properly.
Another ham found the same problem with his Dentron MT-3000a when
using ladder line on 10 meters. See K8JS's post on eham.net below for
his experience with the Dentron MT-3000a internal balun on 10 meters.
The Lazy H antennas work beautifully at 100 watts, but any more than
that and the external baluns begin changing value as they heat up. I
have seen a Hy-Power 4:1 balun rated at 5 KW that claims it can handle
it, and Palomar has a kit claiming to be able to handle it as well.
If possible I would like to build it myself. I get alot more bang out
of a good signal report if it is on equipment I restored/repaired, an
antenna I built, etc.
I also edthe CQ balun/unun book from hamradio.com. Hopefully it will

shed some light on the subject

I will respond in a couple of hours, but in the meantime, please clarify
that everything between the ATU and LazyH is up for consideration.

What impedance line are you using?

Do you feed the antenna midway between the elements of at one element
(branch or distributed feed)? What do you think the feed point impedance
is?

What band(s)?

Owen

I am using 450 ladder line. The Lazy H is center fed with 1/2 wave
spacing between the top and bottom elements and the elements are 1/2
wave elements. 450 ladder line is connecting the top and bottom
elements. I am not using the expanded Lazy H version. This is the
classic center fed Lazy H design as shown in the ARRL antenna
handbook. I only intend to use the antenna on 10 meters. I don't
know what the exact impedance is (sorry). The Lazy antenna is about
50 feet off the ground at the top wire. The amplifier I want to use
with the Lazy H is a Drake L4B with two Eimac 3-500z tubes.

Ok, if we define the feed point to be half way between the dipoles, you
ought expect that the feed point impedance is relatively low, some where
of the order of 50 ohms, give or take some reactance and it is a fairly
balanced / symmetric load. Note that the feed system to each dipole is a
tuned length of transmission line, that makes this a narrowband feed
system.

So, your challenge is to deliver the transmitter a nominal 50+j0 load.

Re the ATU's integral ATU, always regard them as likely to be unsuitable.

Let's regard that, integral balun aside, your ATU is probably capable of matching a fairly wide range of impedances at 10m with reasonable efficiency.

If you objective in using a balun is to minimise feedline direct contribution to radiation, your objective is to try to force equal but opposite currents in each conductor.

An ideal voltage balun will approach that objective ONLY with a perfectly symmetric load. If you think you have a perfectly symmetric load, it is probably because you haven't measured it.

An ideal current balun will approach the curent balance objective irrespective of load symmetry, so it is a better choice for your application.

Why do you need a 4:1 transformation? Depending on your feedline length, the impedance presented to the ATU may be as low as somewhere round 50 ohms, and perhaps as high as several thousand ohms. It might seems good to transform several thousand ohms by a factor of 4... but transforming the lower impedances by a factor of 4 exacerbates ATU losses.

Since wavelength is short, I would be inclined to try to use a feedline length of an integral number of half waves, and an effective 1:1 current balun at the ATU. This minimises working voltages within the balun and ATU (reducing risk of flashovers), without driving high losses in the ATU are very low impedances.

If you think about your own requirements, and finding a solution that fits, you will do better than Googling up HamUniverse articles and the like.

When I calculate the feedline length am I correct in assuming that I
need to take in to account the velocity factor of the 460 ohm ladder
line?

Yes Michael, it is the electrical length that is important.

You can use TLLC http://www.vk1od.net/calc/tl/tllc.php to calculate the approximate length of Wireman's ladder line to give you some idea. If you specify the length in wavelengths, the results will show you the physical length in metres. Divide that by 0.3048 to get feet.

The length is not terribly critical, you are just trying to feed the thing near a current maximum rather than a voltage maximum.

If your balun requirement becomes an effective current balun that need only suite 10m, then a number of options spring up, but a ferrite cored balun similar to a general purpose HF balun, but with slightly less turns is likely to give superior performance for the high end of HF.

If you want to read more on the reasoning behind my recommnedations, I can give you some links.

Why, yes. I usually get crushed. I have occasionally been lucky.

Do tell why you ask. Dare I guess it has something to do with an
ignorant comment or two I've (probably) made about antennas and/or
takeoff angle? ;-)

I did mean "down a few dB," by the way, not "down a few s-units."

http://www.eham.net/articles/23758 is interesting.

I contest occasionally. Mostly on 6m and usually as part of a team
doing the ARRL QSO parties and the similar contests from other sources.

It's really fun because of my center of the continent position, one hop
from almost everywhere.

This year's field day was a ball. I did over 200 Qs on 6m in 8 hours
with 80 watts and 8dBd at 25 feet. 55% of the contacts at a 4A contest
site at the time 6m finally collapsed (around 10PM local).

We had to tear down at 6:30 AM due to thunderstorms.

The reason I'm asking is that 'm considering putting up a 10 dipole in a portable location.

My first week with my HTX-100 mny years ago was a blast, and I've enjoyed operating ever since. Most frustration: Hearing a French Polyneasia at 10 over S9 and being unable to get through due tyo a couple of hundred Califonians (onw skip zone closed) with beam antennas and kilowatt amplifies. 25W into a dipole just couldn't cut the mustard.

Good news.

I tried eternal september.org on Win XP in my shack
and it works. This response is through
them using the Outlook Express client, which I
was using before my ISP shut off its NG server.
Good tip. Thanks.

I notice the spam distractions are absent. Good.

Next trick, getting it to work on the iMac, for which I
do not currently have a newsreader. (Betas of the
next Apple OS are said to have major enhancements
to Apple Mail. Fingers crossed for that to include
a newsreader.)

Regarding your login hassle, it is avoidable. My
news client does it for me automatically and
displays my subscribed groups as folders.

True, Outlook Express is bad, but not ALL bad ;-)

I also tried september.org using the XNews client which offers much richer filtering than you get through most newsreaders... and doesn't have the bottlenecks and stalls that Google Groups has, with or without its new interface.

Why not just use a(n electrical) half wave loop of coax if you are only using
it on 10metres? Or even just a Pawsey stub for a balun and match elsewhere.
You can do a lot of (single band) matching with just a quarter wave of open
wire line with shorts/open circuits and taps.

Dear Group: Very good observation from Owen - as always.

Time for an story, which I hope illustrates several things:
Back over 50 years ago, my great pal at The University (if you are from this part of the Midwest you know exactly what I am indicating) W8BZB had a small, English car. This was only possible for an undergraduate because he lived in town. He installed a little 10 meter AM rig in the car that used tubes and a motor-generator set to get high voltage. Worked into Europe like Gangbusters. One day we got to examining the rig and I noted that the tubes all had 12 volt filaments and the generator was for 12 volts too. His car had a 6 volt electrical system. Anything can work.

Thus ends the lessor about the first rule of HF antennas. 73, Mac N8TT

P.S. The first rule of three-phase motors is never to tighten their couplings until you have verified direction of rotation.

Hi John,

Perhaps I might answer by nominating some that are more dependent on ground.

The classic case would be a monopole worked against real ground, meaning having one terminal of the feed line connected to the dirt in some way.

A centre fed dipole rigged very low to real ground is more depended on ground than one that is higher.

My experience is that if you don't have the time or resources to install a substantial ground system, avoid antennas that depend greatly on that ground system for performance. Driving a short conductive stake, or running a wire along the surface, or running a wire into a body of water does not make an effective ground system for these purposes.

I recently had QSO with a field station on 40m at about 500km distance. Initially he had a half wave dipole lying on the ground, and was somewhat surprised that I could work him with 100W from his tx. He raised the dipole

to 5m (15') and we tried 50mW SSB. He reported that I was essentially noise free at that, but I could not reduce power any further.

We prove time and time again that anything "works", but an antenna less dependent on the ground usually gives more consistent performance.

I've been using Eternal September for about a year, ever since Telus, our local telephone company from which I have ADSL connection to the Internet, dropped Usenet. Like Macs and Subarus, Eternal September just works.

> I notice the spam distractions are absent. Good.

Their spam filtration is excellent. But see below.

> Next trick, getting it to work on the iMac, for which I
> do not currently have a newsreader.

Get MT-NewsWatcher 3.5.3b3. Ignore the beta designation. It too just works. It's Universal, so it worked on my wife's old PPC 2005 iMac and my old PPC 2001 Mac tower both running Mac OS 10.4 (Tiger), it works on our 2007 MacBook laptop running Mac OS 10.5 (Leopard), and it works on my newer 2010 Intel iMac running Mac OS 10.6 (Snow Leopard). There is no reason to think it won't work fine under Mac OS 10.7 (Lion) since it does not rely on PPC code and thus won't need Rosetta, which will be missing in 10.7.

It has excellent filtration capability, though with Eternal September you will have little need for it. I mainly use it to avoid having to look at the postings of a few kooks on this newsgroup.

It automatically connects to all your selected newsgroups when you fire it up.

It's a descendant of the original NewsWatcher program, which came from John Norstad, who wrote the legendary Disinfectant program, so valuable in the days before Macs started using Unix labelled as OS X. You can get MT-NewsWatcher any number of places, the easiest being at MacUpdate. It's donationware, and well worth a modest donation.

Then again, I'm not saying which is which.

It's not hard to tell though. Good advice tends to have the ring of truth to it. It's something you can reference, can duplicate, and at some point makes sense.

The other sort might be mystery physics, like little particles that jump off your antenna to another, the discarding of everything past Volta, or magical 3 foot antennas that work better than anything else.

Then again, I guess I just did say which is which.

Because the windings on a balun is not just turns on a core. They are transmission lines of a specific impedance. Wires of a diameter must be a certain distance apart to make a line of of the desired impedance. If the line is supposed to be 50 Ohms they need to be close together, too close for the thick insulation on house wire. Stranded wire is harder to wind on a ferrite core and maintain the spacing that is needed to make a good balun. Just remember that baluns are not transformers in the classic meaning of the term. They are made of sections of transmission lines. For example a 4 to one balun is made of 2 100 Ohm lines that are connected in parallel on one end, 50 Ohms side and in series on the other end for the 200 Ohm side. The common mode impedance keeps one end from seeing the other at RF frequencies. You can not see this with a Ohm meter!

Change the "or" to "and" and you've got it. It is quanta that pop into and out of existence that acts as a transport medium for EM waves. EM waves cannot propagate without "it" as a medium. That's why EM waves cannot escape the universe - witness the 12+ billion year old background radiation still propagating through the quantum aether to this very day.

The don't ALWAYS use enamelled wire, but yest, it is very common.

I previously reocmmended a 1:1 current balun to you, so I will answer your question in that context. (I do note though that someone has since recommended a voltage balun.)

If you are looking for a 'general purpose' balun to use with an ATU, you should be more interested in a balun that can withstand high voltages than close to ideal impedance transformation.

ECW is a relatively poor choice, and Thermaleze ECW which has a higher nominal voltage rating seems not up to the task at extreme loads. PTFE sleeved ECW or PTFE insulated flexible wires seem a better option for extreme loads.

Stranded wire does have higher loss than an equivalent circular conductor... but losses in a current balun in a practical antenna system are usually mostly due to common mode current causing heating of the core, ohmic losses in the windings are usually much lower and insigificant... though they do commonly feature in published specifications.

Again, more info is available if you want the links.

W5DXP said:

It is quanta that pop into
and out of existence that acts as a transport medium for EM waves. EM
waves cannot propagate without "it" as a medium. That's why EM waves
cannot escape the universe - witness the 12+ billion year old
background radiation still propagating through the quantum aether to
this very day.
==========

I infer that a perfect vacuum wouldn't propagate EM waves. If a clear glass cube (or other hollow structure of your choice) could be evacuated completely, what would I see if I looked at it? Does light propagate through it? Would objects inside it disappear from view? The cube appear to be painted black on its inside walls?

Wrong - a perfect vacuum teems with the quantum soup and therefore
does propagate EM waves. What will not propagate EM waves is the
absence of the quantum soup, i.e. absolute nothingness which surrounds
the known universe..

==========

I see "quantum soup" referred to in the context of the time immediately
after the Big Bang. How would you describe the latter-day quantum soup?
Photons? Something else? Is it of constant density or variable? If
variable, is there an optimum density?

The concept of "no EM waves propagating through nothingness" allows for the
existence of other Universes, about which we can know nothing unless one
begins to overlap our own. Even then, it might take billions of years for
their EM waves to reach us. Interesting to contemplate.

After the time when the universe changed from being opaque to being transparent to EM light waves, a dilution of the quantum soup has occurred. The increase in the wavelength of the Big-Bang energy is proportional to the expansion of the universe. When the quantum soup gets diluted enough to cease its expansion pressure, gravity will take over and the universe will collapse into another singularity - ad infinitum - just as it has "always" been. The quantum soup is like a spring that releases expansion energy for a time and then stores collapsing energy for a time. What could possibly have more inertia than the entire universe?

P.S. It's hard to talk about the passing of time when time is known to cease to exist during a singularity. "How long does a singularity last?" is a nonsense question because time is undefined during a singularity.

Posting-Frequency: posted monthly
URL: http://www.faqs.org/faqs/radio/personal-intro/

Changes followed by "|".

The rec.radio.info newsgroup, first established in 1993, has been
recently revived by an active moderation team. We are currently seeking
suitable information, FAQ, and bulletin articles from the entire
rec.radio.* newsgroup hierarchy for simultaneous cross-posting to our
newsgroup.

We are seeking a replacement maintainer for the following information
bulletin formerly posted to rec.radio.amateur.* (and currently archived
at http://www.faqs.org/faqs/radio/personal-intro/ ):

radio/personal-intro
Subject: Guide to the rec.radio Newsgroups
Maintainer: jeffreyh@Hawaii.Edu (Jeffrey Herman)
Last Posted: 9 Nov 2001 06:18:17 GMT
Posting-Frequency: 15th of each month

One significant omission, requiring immediate updates, for this article |
is that it does not mention newer amateur radio newsgroups created since |
it was written, including: |

rec.radio.amateur.antenna |
rec.radio.amateur.boatanchors |
rec.radio.amateur.dx |
rec.radio.amateur.equipment |
rec.radio.amateur.homebrew |
rec.radio.amateur.moderated |
rec.radio.amateur.space |

We are willing to provide any technical support necessary to get this
article updated and automatically posted again at a regular interval.
This would include establishing contact with the original maintainer for
any necessary permissions. We would prefer to seek a new, dedicated
maintainer at this time, rather than start auto-posting the original
article ourselves.

For more information about our newsgroup, see:

> Oh, yeah?

Simply, the conditions for steady state analysis are not satisfied by TV bandwidth modulation on a long feed line.

This is the reason why some matching schemes that are quite suitable for SSB telephony on feedlines of a few hundred metres are not used with TV on long feedlines.

Hi Guys,
I'm looking over the files at;
http://groups.yahoo.com/group/thedallasfiles/
These antennas are mostly for the AMBC band.
The author doesn't allow discussion on the site,
I wonder if anyone else has viewed these files and
has interest in the antennas and wants a discussion group.
Mikek

Do you mean you don't have an interest in the subject
or do you mean you have a better antenna for the
AMBC band?
If you have a better antenna, let me know, I'm ready to start
building. Ideally I want to rotate a flashlight beam...
but I'll settle for rotating a wide aperture null.

Hi Mike,

The subject is Dallas Files, right?

What does that mean?

I've no interest in playing games with the author who refuses to engage in dialog simply to access files of unknown content. Apparently given the dearth of participation, neither does anyone else. With the absence of discussion at the author's site, there is no interest there either.

Now, if you care to describe what you have come to learn, that is another matter. I presume by implication alone that this is about small, beam stearable, receive-only antennas. Unfortunately, there's a lot left unsaid.

Hi Richard,
Ya, the author has no interest in engaging, he just posts what he has learned. The site was recently moved to Yahoo and is only about 2 months old. As for the absence of discussion on the site, it's not allowed, so that is hardly an indicator.
Yes, I'm looking a steerable receive only arrays for the AM broadcast band. Myself, I want one that will fit on a 150ft lot.
Sounds like you didn't look at the site so "what is left unsaid."

Thanks, Mikek

URL -- http://www.vvdailypress.com/news/shot-28670-feud-fired.html

Shot fired when neighbor feud escalates

July 05, 2011 1:01 PM

PINON HILLS • A Pinon Hills man is behind bars for attempted murder after allegedly shooting into his neighbor•s home following an argument, San Bernardino County Sheriff•s Department officials said.
Baron Smith, 47, became involved in an disagreement with his neighbor Sunday and it escalated, Jodi Miller, spokeswoman for the sheriff•s department, said. According to reports, the neighbors had been feuding for some time. •This is an ongoing fight and this time it accelerated to that level,• she said. Authorities received several reports of a man shooting toward a house in the 2500 block of Olivera Road at about 6:30 p.m., according to Miller. When deputies arrived, they learned Smith had gone back to his home across the street from where the shooting had taken place. Officials went to the home and arrested Smith.
The Pinon Hills man was booked into Victor Valley Jail for attempted murder. He•s scheduled to be in court Wednesday.

--

The unnamed individual is Frank Rossio older brother of screen writer
Terry Rossio.

On 3840kHz the below between July 1 and July 11 between the hours
of 9:00PM (PST) and 4:00AM (PST) all the below individuals below

KI6GPR, (Cosmo - John), of Santa Clarita, CALIF
NO6L , Charles (Chuck) G Ruff of Tehachapi, CALIF
KI6DKV, Noel W Burman of North Hollywood,CALIF
KK6FR, Frank Rossio of 2540 Olivera, Phelan, CALIF

have stated that Frank Rossio (kk6fr) will own Baron Smiths property,
and all have used a gang like character assassination against Smith.
There is some collusion with the individuals above and Frank Rossio to
illegally obtain Smiths property.
The individuals above should be investigated.

ALSO consider

point one - Rossio owns the defunct FG Bestcommunications, a company
that entitles him to obtain dangerous chemicals and may be fraudulently
using his business license to claim tax exemptions. In August of 2010
AD8Q Kevin Caprio, drove to Phelan and purchased some equipment

from kk6fr then returned back to Arizona dropped dead shorty thereafter after complaining of massive headaches.

point two - ke6ynh, Tom from San Diego got into a big argument with

kk6fr and no6l about November of 2010 on 3840kHz. Both Frank Rossio and Ruff threatened to drive down and kill Tom, well in December 2010, passed on from mysterious causes. Ironically when the two silent keys died, Frank exhibited no apathy and even praised their deaths. In regards to Smiths arrest he bragged about it and mentioned "his (Smiths) property is as good as gold his (franks)."
Something is going on! Frank Rossio and his clan of cohorts needs to be investigated. KK6FR is nothing but a liar, braggart, punk, who threatens people and exhibits a schizoid personality, one trait is his lying and contorting stories, no different than a con man!

DO NOT BELIEVE EVERYTHING FRANK ROSSIO SAYS IT'S A
RUSE. IF YOU ARE A HAM YOU'D BE ADVISED TO AVOID ANY QSO
WITH THE ABOVE INDIVIDUALS.

Hi Mike,

As I said, nothing there but a vague suggestion of the topic heavily cloaked in an admonition.

> Yes, I'm looking a steerable receive only arrays for the AM broadcast
>band. Myself, I want one that will fit on a 150ft lot.

Is that 150' on a side? 150' long?

There are any number of ways to construct variable delay lines. A little bit of computer control will pull their outputs together to form beam steering.

Planting the antennas is simple and allows for testing of any of those many ways to construct variable delay lines. Those designs themselves have various trade-offs for issues you need to prioritize and pronounce. The antennas don't need to be in any particular, regular pattern as that would be accommodated by computer alignment.

If you choose to go manual steering, with analog variable delay line designs; then, yes, having a regular pattern of element layout would reduce complexity.

How many antenna elements? At least three, I would suspect. From there on it is a matter of how well you can resolve the various delay angles for steering a broad beam angle. Increase the number of elements and the beam angle gets progressively tighter. You don't say how much directionality you want, but it will be intimately correlated with this count.

The delay lines will have to be tolerant of mutual coupling - better yet, they should not perturb the existing mutual coupling at all. Good isolation amplifiers between each element and its delay line before going to a summing amplifier would seem a solution. Tracking between delay lines will affect beam width. More elements will require tighter tracking.

Then there is something simpler, an Adcock Antenna and the Bellini Tosi Antenna (about 100 years old, but does the job too). There is the Krug (Wullenweber) antenna. They are all symmetrical designs that simplified the manual, analog delay lines design.

In the end, they all comprise the same fundamentals. If you cannot support a symmetrical design, that is your primary limiting factor. If you can digitize the delay lines, then symmetry can be synthesized and the antennas can be placed physically anywhere limited only by the resolution of digital sampling rate.

1742. Broadcast Tower Hoogersmilde (Netherlands) down due to fire.

Newsgroup: rec.radio.amateur.antenna
Date: 2011-07-15 16:01:36 UTC
From: Wimpie <wimabctel@tetech.nl>
Message-ID: <37edd$4e2063c2$5355cc82$2943@cache100.multikabel.net>
Source record: 4293

First there was a fire in the 300m IJsselstein (lopik) tower, some hours later there was a fire in the "Smilde" tower (also about 300m/980ft).

The construction (Smilde tower) couldn't resist the heat and collapsed, see the video.

http://www.youtube.com/watch?v=VdMLiL4vlHc

Now 80% of the Netherlands can't get national radio over the air (as the Lopik tower is still inoperative because of investigation).

You cast dispersions, but haven't looked at any of the antenna
systems. Look at just one and see if you any thoughts.
Look at "Hi Z PPL Loop And Flag Arrays.pdf" it's the 5th file down
on the antennas page.

Are you aware that steering the null is very important for AM
band dxing?

Hi Jeff,
Why didn't the loop sizes shrink, when the author went from 1296Mhz
to 2400Mhz. First thing I thought about was etching it on a PCB.
But then saw he built the higher freq antenna with the same loop
lengths.

Hello Michael,

It isn't snake oil, but with many elements, it is difficult to get it
working in practice. Such structures are narrow band and you don't
have a single tuning point to correct something.

If you plan to build an existing antenna, make sure to make a real
good copy of it. Just a good SWR doesn't automatically mean you have
the correct current distribution to get the stated gain.

With kind regards.

I'm not quite sure what you mean. However, I have a guess(tm).

>> His curtain quad calculations and NEC2 deck are at:
>> <http://home.comcast.net/~ross_anderson/CurtainQuadFigure11.htm>

If you scroll down to the bottom of the NEC deck, you'll find the
line:
FR 0 1 0 0 1332 0 'simulation is at 1332 MHz
That's the operating frequency. Change it to 2442 MHz and you have a
2.4GHz antenna.

The element dimensions in the NEC deck are in wavelengths. This makes
it very easy to use a design on different frequency. In order to
obtain construction lengths, simply multiply each element length by
the free space wavelegth. For 2.4GHz, that's about 12.5cm.

. .. and it looks like he has a serious hard-on for anybody who's a ham
or an engineer or both. I applied to join the group, stating those things
about myself and saying I had a lifelong interest in improving radio
reception. I don't recall that I said anything else.

Here's what happened next (quoting from yahoo's email to me):

Hello,

Your request to join the thedallasfiles group was not approved.
The moderator of each Yahoo! group chooses whether to restrict
membership in the group. Moderators who choose to restrict
membership also choose whom to admit.

Please note that this decision is final and that Yahoo! Groups
does not control group membership.
< remaining form-letter chatter snipped >

Doesn't make a whole lot of sense
to me. I planned to be an asset in his group. Anybody
have the same experience or am I special? ;-)

Ah.. I'm still confused, For the 1296 antenna he used 2" x 3" fence
material and then the same 2" x 3" for the 2.4Ghz antenna except for
wire diameter.

That's just the reflector material. Quoting from the above URL:
"The antenna is constructed from 3 inch by 2 inch galvanized
welded wire fence. Wire radius is 0.039 inch."
The reflector is not sensitive to the wire spacing as long as it's
sufficiently small. You could use chicken wire, wire mesh, metal
window bug screening, a barbeque grill, etc for the reflector. I used
some gastly 1/4" galvanized wire mesh, covered with aluminum foil.
For 1.2Ghz, his relfector is 28x21 inches. For 2.4Ghz:
<http://home.comcast.net/~ross_anderson/2400MHzAntenna.htm>
he didn't mention the size of the reflector, but it would half the
size of the 1.2GHz reflector.

This all seems odd to me.
I had no problem getting admitted, he works with several hams regarding
his antenna systems, so it's not about hams.
I think he has some great research using single, dual and quad phased
Flag or Delta antennas. There's also info on building a circuit for
adjustable phasing of two antennas.
So get another email address and just say you have an interest in
improving your AM radio reception.

Copied and pasted from the Curtain site.

13 element Curtain Quad for 1296MHz described

The material list is as follows:
---
3 inch by 2 inch welded wire fence (from Orchard Supply Hardware).
The wire radius is about 0.039 inch, which is what #14 steel wire is
when galvanized.---Foam insulation 2 inch thick

And then the parts list for the 2.4Ghz antenna
...
3 inch by 2 inch welded wire fence (bought locally from Orchard Supply
Hardware). The wire radius is about 0.031 inch, which is what #16 steel
wire is when galvanized.--- Foam insulation 1 inch thick
...

As you can see the loops lengths are the same, 3 inch by 2 inch
size. The wire radius is reduced from 0.039" to 0.31" for the 2.4Ghz
antenna, and the reflector distance is doubled.

I can't tell if maybe he has cut out wires on the 1296 antenna
to double the area, no that would quadruple the area.

This will be my last attempt to understand, so give it one more shot
to inform me. :-)
Thanks, Mikek

But, yet, I got turned down again, even though I fully complied with his directions. The problem is that I politely added my opinion that his methodology for rejecting his group's applicants had a flaw in my case. (He had earlier explained some of it to me in a thoughtful and candid private email.) Obviously, I should have kept my opinion to myself. I live and learn.

He responded to me with a curt one-line private email saying that the flaw was in _my logic_. From that, coupled with his third rejection two minutes later, I conclude that the mere mention of anything negative is an instant deal-breaker. He had earlier described trouble he'd had in his group with people he termed "bad boys." It's much easier to be dubbed one of his "bad boys" than I would have guessed. Wow!

Yes, I could try to trick him with another email address; however, since I'm not welcome at his front door, why risk the humiliation if he catches me prying open a back window? I'm already somewhat annoyed at myself for this missed opportunity. Why make it worse?

OK, so the final score is Dallas 3, Me 0. Game over. *sigh*

Well it is worth it, if you have an interest in broadcast band phased
receiving antennas. Once your in, you can download the pdf files or just
look them over to your hearts content.
I was just hoping for someone else to talk nulling antennas with.
oh well,
John if you send me a private email, I'll send a sample or two
of what's on the site.
Thanks, Mikek

I wouldn't say that. I don't know! Give it a try.

Academically, he certainly has credentials. I easily discovered article references showing he holds a PhD in Mathematics. He's a current university professor and a widely regarded antenna expert.

I think he just doesn't tolerate people who cross him. I can't, in good conscience, condemn him outright for that. Maybe he's just over his lifetime toleration for the behavior of smart-ass 18-year-olds (and anybody else that doesn't fly right).

Nope, that's not the "loops" or what I call the "spider web". The
fence wire is the meterials for the reflector, not the spider web. No
clue why the wire gauge changed. I used both insulating foam board
and 1/4" galvanized wire cloth.

Incidentally, I was wrong about the NEC deck being in wavelengths.
It's in inches, which is not my favorite way of doing it. I have a
version somewhere where I converted it to wavelengths. Digging...

All I could find is the original 1.2Ghz desk. See:
<http://802.11junk.com/jeffl/antennas/Curtain-Quad-13/index.html>

> I can't tell if maybe he has cut out wires on the 1296 antenna
>to double the area, no that would quadruple the area.

Yep. Double the frequency and all the dimensions are half. That
creates an antenna with 1/4th the area.

>This will be my last attempt to understand, so give it one more shot
>to inform me. :-)

Incidentally, when I built the 2.4Ghz version, it resonated too low in frequency. I eventually discovered that my bending fixture (graph paper, plywood board, and plenty of 10 penny nails) resulted in a bit too wide a bend at the corners, thus elongating the elements. The 13 element calculated gain was 16dBi. My measured gain was about 14dBi which isn't too bad considering my marginal method of measurement. Photos when I find where I buried the antenna.

Now you see why I will not have anything to do with a
"group" that you must sign up for. Never have, and never will.
Many of them seem to like to play their silly games, have
control over what is posted, banish the hecklers, etc..
No way to live as far as I'm concerned.
And I don't need him to learn about phased broadcast
band antennas. It's not like he invented them or anything.
He's just tinkering with a few, and I presume posting his
results to the few that he deems worthy.. :/

Almost sounds like arson if fire pops up in two of them
hours apart.
Kind of reminds me of one we had fall several years
ago. But it was taller than that one. About a 2000
foot job, and it killed seven people that were assembling
it at the time.
Here is some old video of it.. This is just a few miles
from my house. I can see them from here if no trees are
in the way. There are several tall BC towers out at that
senior road site.

Sorry Jeff, I need to try again,
Either I'm doing a very poor job of explaining my lack of understanding
or maybe we are looking at two different pages.
If you look here;
http://home.comcast.net/~ross_anderson/2400MHzAntenna.htm
you will see the FENCE is used as the ANTENNA ELEMENTS and aluminum foil
used as the reflector.
But the fence loops >seem< to me to be the same size for both 1296Mhz
and 2.4Ghz antenna.
Mikek

Much as I enjoy conspiracy theories, the current guess is overheated
cables:
<http://sw-radio.blogspot.com/2011/07/overheated-cables-thought-to-have.html>

More tower wires, most of which were caused by workmen using a cutting
torch on the monopole, and igniting the polyethylene insulation in the
coax cables:
<http://802.11junk.com/jeffl/SCCARC-talk-2010-06-18/Burning-Towers.htm>

Hello Mark,

I thought the same, but according to the current info (speculation?),
it wasn't arson.

At this moment there is no info on the Dutch Safety Board's website
(www.onderzoeksraad.nl), so we have to wait for real info.

The Senior Road FM/TV tower;
Really bad that "some" miscalculation resulted in overstress in a
U-bolt with such horrible end-result. There is lots of info on the web
regarding this accident.

Thank you for sharing your info,

Wim
PA3DJS
www.tetech.nl
Please remove abc first in case of PM

PS: I spent lots of hours with FS98 (mostly IFR and misusing jets as gliders).

Yup. Such groups are very orderly but sometimes
"free-swinging" is more productive.

I concur with your observation, Mikek. It may be that Jeff has looked only at the first listed reflector which was identical to the antenna itself.

Both the 1296 and 2.4gHz antennas use the same fencing material.

Nope, my mistake. Brain damage and assumption on my part.

<http://home.comcast.net/~ross_anderson/CurtainQuadFigure11.htm>
<http://home.comcast.net/~ross_anderson/2400MHzAntenna.htm>

I didn't use the recommended fencing material. Instead, I made mine
from some #16 awg solid copper wire, soldering the junctions together.
When I built the 2.4GHz version, I scaled it from the 1.2GHz
dimension, resulting in NOT using the 2x3" fencing material. I then
built it without looking at the original article again. I'll dig
deeper and see if I can find the 2.4GHz antenna and design data.

That brings me back to the original question, which is how can both
antennas be made from the same 2x3" fencing material. I'm not sure
what's happening because the drawings are not fully dimensioned. I
also just noticed that the grid paper shown do not match the
dimensions listed in the NEC deck. Logic (and guesswork) would
suggest that if the 2x3" mesh was used for 2.4GHz, then every other
wire could be used on 1.2GHz, forming a 2x6" mesh. However, I can't
tell from the dimensioning. I'll try to transplant the dimensions to
a common drawing, and see if it can be decoded.

Gone to do some chain sawing. More if I survive.

In trying to avoid such a simple request, you deny yourself
a great many sites.

> Many of them seem to like to play their silly games, have

I don't see this as reason to deny yourself access to
hundreds or thousands of sites that have great information.

> And I don't need him to learn about phased broadcast
> band antennas.

I want to learn, do you have any sites with good broadcast band antennas.

It's not like he invented them or anything.

He's not claiming invention, but he has made a nice
contribution to the hobby.

>

Tinkering seems a little insincere, I'm sure he ha smany hundreds
of hours into his research.

Please post any websites you have regarding broadcast band antennas.
I have not found much other than resonant loops and beverages.
Mikek

Who says it's all great information? Some may be. Some
may not. I'm not going to jump through hoops to find out
one way or the other.

>
> > And I don't need him to learn about phased broadcast

He probably does. But what does that have to do with me?

>
> Please post any websites you have regarding broadcast band antennas.
> I have not found much other than resonant loops and beverages.
> Mikek

Already gave one example above. I think W8JI was using
some sort of steerable verticals, and he might have some
info on his site. As I recall, they were pretty short,
and maybe not even resonant, but I don't recall how he
was steering them.
There is tons of stuff out there.. And there is always
that source many seem to ignore these days. Books.

Myself, I happen to like loops.. I'm more interested in
a good null, than I am a really directional pattern like a
flashlight. I don't have the room to run a decent beverage
here. I can do it at my dirt patch out in the sticks, but
I've never got around to stringing the wire up.
I intend to do it one of these days just to give em a try.
Anyway, I've been fairly satisfied just using the various
loops I have for general AM-BC use.
If I decide to build something a tad more exotic, I'll
dig up the info, and I won't be jumping through hoops to
get it. Plenty of other flag array users out there.
No need for me to bother Dallas about it.

For receive only, and moderate bandwidth, then digitizing the multiple antennas and doing the phasing in software is probably the easiest approach. Essentially infinite variability, you get "true time delay" as opposed to phasing (the latter is inherently narrower band, although for AM BC band, it might not make any difference.. 150 ft is a tiny fraction of a wavelength).

In general, you can place N-1 nulls with an array of N antennas. Broad nulls (in angular extent) are done by stacking multiple narrow nulls. For AM BC band (which is like 160m ham band), gain isn't a big deal, you'll be interference and atmospheric noise limited.

The usual scheme is to use a lossy short untuned antenna and a FET pre-amp. There are several nice designs out there, or you can buy them off the shelf.
http://www.amrad.org/projects/lf/actant/ is an example

Here are 2 good ones that I frequent and their email addresses.
1) SkyWires in yahoogroups <SkyWires@yahoogroups.com>

2) Loopantennas in yahoogroups <loopantennas@yahoogroups.com>

You can also do a search from the Yahoogroups find a group pages for "Loop antennas" "BCB" "AM radio" & "MW" to name a few.

how deep a null, how narrow/wide?

One of the noise canceling boxes with two antennas will do quite well.
Timewave ANC-4 is one possibility
MFJ 1026 is another.
DX engineering NCC-1

For BC band, almost any antenna will work.

If you want physically small you could use any of the active antennas..
You could use a MFJ1020C,1022,1024, Ameco TPA, DX Engineering ARAV3-1P, etc.
The MFJ 1026 canceller includes an antenna.

A whole bunch of kits out there..
Ramsey AA7B, the Amrad antenna, ..

If you want to get more sophisticated, some sort of software receiver
might be better approach (you could use more than 2 antennas, for
instance). There's not much off the shelf, but if you're ambitious you
might look at K1LT's array using softrock receivers.http://www.k1lt.com/

In BCB SWLing you want the null(s) deep (and steerable)
to kill the strong, unwanted station.

Source record: 4333

Hi,

Just getting back on the air after many years of silence and I find myself struggling over the choice of antennas. I need something that I can easily raise and lower (get out of site due to CCR rules) so we're talking about a compromise. I do have room for a couple of radials (max 30 ft) as long as they can buried in the ground 180 degrees apart (not ideal). The antenna will have to be installed within about 4 feet from the side of my house. I was hoping to find a self supporting vertical betwwen 30 and 40 ft hight that could pivit at the base (might need to purchase that separately) so it can be laid down flat on the ground next to the house when not in use. I plan on purchasing an auto tuner if necessary. The vertical can have no physical radials on the antenna itself.

And by the way, I live in the hills above Henderson, NV so the quality of the ground isn't good; lots of rock and hard clay with poor drainage.

Purchase price up to $400.00 OK. Any ideas of what might work in my situation?

Many thanks in advance!

This characteristic demands the SAME considerations as required for a sharp beam of high directionality.

If we were to select the antenna that matches your quoted specs above, it would be called the Cardiod (example available in EZNEC). Problem there is the 30dB null isn't steerable (not enough elements). And it is large (too large for the back yard):
1. Too tall for most to build.
2. Elements too far apart (out of necessity for, dare I say it? Phasing).

As it is designed as a transmit antenna, too tall is quickly dismissed. You can use as short of one as proves useful.

The first element, now being shorter, also allows us to add any number of shorter elements in an array around (or mixed in with) the first. This brings steerability. The more elements, the better angle resolution and null depth control.

You can pull the additional elements (if only one more to build a proof of concept Cardiod) closer to the first (dismissing the large spacing objection), and introduce the necessary time/phase control through:
1. cabling;
2. analog delay circuits;
3. digital delay circuits.

Moving to a digital solution controls all variables.

If none of this is covered in the "Dallas Files," it would be best to leave them in the File Cabinet. Jim has provided adequate links to fill in the gaps and no one was injured in the process of obtaining the information.

Some thoughts on the subject...

If you are going to have an auto tuner, the antenna itself need not be
anything more than a piece of tubing.

I have a 34 ft piece of tubing with a SGC-237 and that tuned 160 (kind of
marginally) through 10 with no problem.

I added a relay controlled loading coil to switch in for 160/80 and now
it tunes 80 faster and 160 no problem.

If your main interest is the lower bands, just make the tubing as long as
you can get away with and let the auto tuner deal with it.

If it is next to the house, drive in as much ground rod as you can and use
a garden drip system along with some flowers or whatnot around the base of
it.

Whatever radials you can install are better than nothing.

Hi Jay,

Google for "Sleeve Dipole" (a vertical) which consists of staged
tubing, the upper element insulated from the lower. Do not connect
the lower element to ground. Thread the driveline coax up inside the
lower element and connect the shield to the top inside of the lower
element. Connect the coax inner lead to the bottom of the upper
element.

As I said, google for images as this description may frustrate you.

Invest the rest of your money (after buying sufficient quantity of
tubing) in your tuner. You may still have a lot left over.

Actually, no.
You can form a deep null with a much simpler antenna system than for high directionality.

All you need is to "cancel" the signal from the undesired direction.

If you had two verticals spaced some distance apart, fed by equal length transmission lines, and one is polarity reversed, you get a fairly sharp null on the line perpendicular to the line between the antennas.
(e.g. a signal coming from broadside will exactly cancel in the combining)

A loopstick antenna on a ferrite core or a multiturn loop, as popular in direction finding, is another example with a fairly sharp null.

Now.. if you want one null, and one null only, that gets a bit trickier in a small space. I don't know that you can do it with only two elements (haven't thought about it much).

And if you want to steer the null.

One traditional approach in direction finding is to use a goniometer or an adcock array.

that's the "one null and one null only" problem.

Pivoting is easy. You can buy a nifty thing from a variety of
suppliers, or you can use a couple pieces of 2x4 and a gate hinge.

Or, if you're stronger.. you can use the removable tetherball pole
approach: a pipe in the ground as a socket, into which you plug the
antenna pole.

A gate hinge with a removable pin (a standard door hinge works, too) is
nice, because then you can actually disconnect the antenna and carry it
away if you like.

You could probably adapt a "swing away" bike rack too.

I plan on purchasing
> an auto tuner if necessary. The vertical can have no physical radials
> on the antenna itself.

Autotuner and vertical is a great combination (if the tuner is at the
base of the antenna, particularly)

>
> And by the way, I live in the hills above Henderson, NV so the quality

The only problem with "long antenna on high bands" is that the pattern
gets kind of wonky. If you care about this, then something like a 6BTV
trapped vertical might be a better solution. Still with the autotuner
(because it means you don't have to worry about the adjusting the
antenna or it changing as the soil moisture changes, etc.)

>
> Purchase price up to $400.00 OK. Any ideas of what might work in my
> situation?

Galvanized Fence Top Rail is a very cheap pipe available in 20 foot lengths.

EMT (thin wall conduit) is another.

If it's next to something (the house?).. how tall is the house? Can you
just suspend a wire?

That should get you started...

Richard, isn't this pretty well what the GAP antenna does ??

Jim K4PYT

Hi Jay,

Google for "Sleeve Dipole" (a vertical) which consists of staged tubing, the upper element insulated from the lower. Do not connect the lower element to ground. Thread the driveline coax up inside the lower element and connect the shield to the top inside of the lower element. Connect the coax inner lead to the bottom of the upper element.

As I said, google for images as this description may frustrate you.

Invest the rest of your money (after buying sufficient quantity of tubing) in your tuner. You may still have a lot left over.

Something I've already offered (Bellini Tosi Antenna, as well as
Wullenweber) - and has been rejected/ignored. Repetition doesn't seem
to stand much chance against the ongoing cult examination in trying to
parse the entrance qualifications for the Dallas Files.

Hi James,

Yes, in large degree given my experience with the Gap Eagle. I figure
it would draw more than the usual attention, and become a target for
the covenants, deeds, and restrictions.

The antenna would be about 4 feet away from the house. The house is 20 ft high at the peak of the roof (single story). The roof is concrete tile. I've looked into suspending a wire from a telescopic pole but it seems like it would be a little cumbersome to raise and lower. I've looked at suspending a long wire between front and back yard trees but that is a little more permanent and the HOA could bust me if they saw it. This is why I'm thinking a vertical would be less visible, easier to setup and take down, and has a fairly small wind load. I do favor 20 - 10 meter bands so that might be a prob elm for the design I'm considering. I love the fact that cheap, small diameter pipe can work as well as a commercial product. Thanks for that info!

One of these for 10m was the first HF antenna I ever built. I wish I had known then about decoupling the feed line, as I never could get repeatable VSWR data, possibly due to common mode current. Maybe I'll rebuild it and try again with a suitable choke.

I read about the sleeve dipole before I built it and I will pass on a caution: The end where the cable comes out is a high voltage point (expected for the ends of dipoles); higher powers may punch through the coax outer jacket to the coax shield. I use a piece of PVC plumbing pipe as additional separation inside the lower element and never had an issue.

"Sal"

Happy building.

Richard - Is there such a thing as a multi-band HF sleeve dipole or is
this more of a VHF/UHF solution?

Jim - You've given me new hope! How significant is the length and depth of the radials? I probably have about 30 feet each way along the side of the house. Are you suggesting a drip system around the ground rod to improve the quality of the ground or for decorative reasons or both?

I don't have any CCR problems but I do have a vertical antenna of
about 28 feet cobbled together and the SGC-237 does a great job with
it. The SGC-237 is pricey but I don't think it can be beat.

Several years ago I used 4 fifty foot extention cords on top of the
ground for radials and it did work. I experiment with antennas a lot,
so everything at my qth is always changing.

Perhaps you can glean a little inspiration from
http://dixienc.us/28FtVert/28FtVertical.htm

There are some nice light weight fiberglass whips on the market in the
$100 range. One of these days I will follow that path.

The depth is deep enough to cover them with dirt.

Since they are buried, the absolute length isn't particularly important, just put in as many as you can as long as you can in whatever directions you can.

The optimum case would be if they were under a lawn that is watered, otherwise you just do what you can do.

From my point of view the drip system improves the ground while the XYL may have a different viewpoint.

In my case, there is a small copper plate at the base of the antenna that interconnects the ground rod with all the radial wires and is the ground point for the tuner.

There is an old picture at http://mail.specsol.com/~jimp/ant_base.jpg

This one doesn't fold, but it would be no big deal to make that way.

The upside down trash can covers the auto tuner.

The low band loading coil is 1/4 inch copper tubing I happened to have wound on a PVC mount and form. The switching relay is inside the coil form at the bottom.

The loading coil was trial and error adjusted for best SWR on 80 without the tuner in the circuit.

The PVC pipe going into the ground has the antenna coax and control lines for the relay and auto tuner in it.

The ratty looking braid from the ground rod going up into the trash can has since been replaced with a #6 wire to the plate.

If 20 meters and up is your primary interest, instead of a base fed
vertical make it a vertical dipole with the length based on 20 M.

This has the advantage of not having to have a RF ground.

>this more of a VHF/UHF solution?

Hi Jay,

It is multiband if your tuner can pull the SWR into reasonable limits.
However, you do NOT want the overall length of the antenna to exceed
roughly a 1.25 wavelengths of the highest frequency you intend to
multiband. This is for two reasons at that frequency:
1. Difficult to tune at 1 wavelength;
2. Radiation is directed up at a high angle if longer than 1.25 wl.

Please read Sal's perceptive comments about hi voltage exposure; and
observe his statement about choking the line.

Futher, and this complicates the simple rules above, your sleeve
dipole does not need to be made of equal length elements. This raises
the prospects of another topic:
Vertical, Off Center Fed Dipoles.

As for building ground radials - skip that wasted effort. You have
too little footprint available, and your ground isn't conductive
enough to present that much loss. This is why I suggested the sleeve
dipole.

Yes.

Mine was mounted with the end of the bottom element within reach from the ground. I lengthened just the bottom element experimentally with a simple clip lead -- and that worked. Sometime "cheesy" works. :-)

Cardioid has only a single null and is a "end fire" configuration. I
don't think (esp with short spacing) you can get as deep or narrow a
null as with a W8JK style antenna(short spacing, out of phase).

two 180 degree out of phase antennas can be very narrow, even with small
physical extent.

If you've got a tuner, you don't care about the absolute length of
anything. That makes life much easier.
You put in what you can for grounding. more is better, but whatever
works.. drip irrigation is for conductivity.

If you can snuggle one of your radials up against your concrete footing,
that helps Concrete is a fairly decent conductor because it tends to
hold moisture and it has large contact area with the soil. If you're
pouring a slab for a patio, put some wires in it.

I favor the SG239... it's cheaper, and I can fabricate a weather proof enclosure for a lot less than the price difference to the SG-237. SG239 handles twice as much power, for all that's worth.

Electrical conduit, or PVC pipe with some wire on or in it are other ideas.

Conduit is about as cheap as you can get, and it's available in lots of different sizes. It's light weight too, so putting it up and down is easy.

Yes, it won't stand up to a hurricane.. but hey, you scrap your $10 investment in cheap galvanized steel and buy some more.

And put your autotuner in the middle at the feedpoint. Get yourself a
batch of 31 mix toroidal cores to make some chokes, too.

You might want to consider a magnetic loop antenna -- easy to build and
conceal.
Multiband might be difficult, but a small 1m diameter loop can easily cover
20 through 10m.
Google 'magloop antenna' and 'magnetic loop antenna'

Hello 1st post here.

I have made 20 meter delta loop.
What I am thinking is...
If I also make a 40 meter loop, and a 10 meter loop, putting them either side of the 20 loop. As in the 20 loop in the middle. The 40 behind, the 10 in front.
With suitable spacing, all strung on 3 fishing poles.
Will this work as a directional beam of sorts hopefully all 3 bands.
I am hoping 3 traditional elements on 20,
even driven element on 40 /with 2 directors,
and on 10 with 2 reflectors.
I know the lengths of the director's and reflectors won't be as standard but with a tuner does anyone will it work to a degree?

Just kicking the idea around.

Anyone done it before?

thanks' for any help or suggestions.

But, nothing; that's not the way things work. To get beam action,
there is a very strong correlation between element size, element
orientation, separation distance, and wavelength. Size and distance
are on order of fractions of a quarterwave, not multiples of
wavelengths.

>with a tuner does anyone will it work to a degree?

A tuner is for tuning (getting the SWR to a reasonable match). It has
nothing to do with antenna directionality.

I think you'd need to model it out with NEC to see if it would work.

I'm unclear as to whether you're planning to have separate feedlines
for the three delta loops, or whether you were thinking of just
driving one of the loops on all three bands and having the other two
loops be entirely passive. If you are thinking of driving the three
loops separately, I'm uncertain what you intend to do with the other
two loops - leave the feedlines open, short the feedlines, or
disconnect the loops from the feedlines and short the loops closed at
the feedpoint.

You'll be facing a few significant issues, when trying to use the
un-driven loops as directors / reflectors. For the sake of simplicity
I'll assume that the un-driven loops will be purely passive loops of
the expected length (e.g. no feedlines, or with the loop shorted
closed at the feedpoint).

For example, on 20:

- The 10-meter loop is going to be only a half-wavelength long. It
won't resonate (or be anything close to resonance), but will
instead have a low radiation resistance and a very high reactive
impedance. As a result it will probably be almost "invisible" at
20 meters, and will not carry enough currents to affect the pattern
significantly.

- The 40-meter loop will be about 2 wavelengths long. Although it may
be at (or close to) a second-harmonic resonance, the currents in it

would not line up well with those in the fundamental-resonance 20-meter loop, and the effect on the main loop's overall radiation pattern would probably be quite weird.

Similarly, on 40, the two smaller loops will be highly reactive and thus almost "invisible". On 10, the two larger loops may resonate, but with current patterns which don't add well to that of the 10-meter loop and thus affect the pattern in weird ways.

There's another option: use some nested passive delta loops. Mount a second 10-meter delta loop (tuned a bit lower in frequency than you normally operate) suspended inside the 20-meter delta. Mount a second 20-meter loop (again, tuned a bit on the low side) inside the 40-meter delta. This would give you the effect of a two-element beam (radiator and reflector) on 10 and 20 meters, without affecting 40-meter operation significantly.

Hard to know exactly what you're planning on building. Are you going to have 3 loops, one for 10, one for 20, one for 40 arranged in a row, sort of like rings on a post?

If you had a tuner on each loop, one might be able to get it to work. For instance, one can build a Yagi with 3 equal (or arbitrary) length elements and use L or C at the centers of the elements to get the phasing right.

The problem with 3 loops of radically different size is that the L and/or C might be impractically large/small to get it to work.

With a bit of work modeling, you MIGHT be able to come up with a single L and C per band for each element, so you could use some sort of simple "two relays per loop" scheme.

Source record: 4222

I'm helping a friend build a very simple portable VHF antenna for hiking. Ignoring all the ladder line J-pole antennas on the web, I decided a simple coaxial antenna would suffice. Remove 19.2" of outer jacket, peel back the braid over the outer jacket, tape, and instant 75 ohm coaxial dipole antenna. However, I'm not sure if the driven element cut length is the free space 1/4 wavelenth, as it would be with a metal rod coax antenna, or if I should include the 0.67 velocity factor of the coax dielectric covering the center conductor. Is it 19.2" or 12.9" for the driven element? My sense of smell says 19.2" but I'm not sure and can't find any specific references that deal with the problem.

Note: I would normally test this on the bench with a reflection coefficient bridge and sweep generator but I have another project going on the bench and don't want to move or touch anything right now.

Use the 0.67 VF on transmission line currents. Use VF = 0.95-0.97 for
antenna currents.

Hi Jeff,

Ah! The sleeve dipole re-emerges.

The exposed wire isn't much different from any other insulated wire
antenna. Air dominates the dielectric constant to the now remote
braid and the plastic ever so slightly shifts things. EZNEC includes
modeling insulated wire.

More's the issue of the dielectric coefficient of the braid pulled
back over the outer jacket of your coax. Coupling issues to the
insulated braid there too shift dynamics - and probably dominates the
DC characteristic.

I usually cut long, and slowly snip the exposed wire until SWR
improves. Choking the line would stabilize this.

First, the design you are looking is NOT a loop (nor loops).

The design you are looking is NOT a beam.

The design you are looking is NOT directional.

Aside from that, it has been around for a while, and satisfies many.
You may be one who would be happy with it, but that is obscure until
you tell us what you want to achieve without trying to shoe-horn in
presumed solutions.

The simple explanation for the design you have linked to is that it is
a "Fan Dipole." The fan is found in the common feed point (at the
left) supporting paired wires for each band spreading (fanning) out.
What makes it unusual is that it is wrapped into a box-like footprint
(without the ends meeting, look closely at the photo). The wrapping
also changes the usual dipole radiation characteristic from dipolar
(radiating in two major lobes) to nonpolar (radiating in all
directions).

Do you have a call sign?

Another solution I've tried is to put a choke on the line that I can
slide along its length (and later tape down). I then put a connecter
at the far (antenna) end of this line. I then put a bare/insulated
wire on a female connecter and mate the two. This preserves the line
from stripping and peeling back.

I cannot vouch how effective this is as a "Sleeve Dipole" in all the
standard characteristics. The Choke Z would have to be very, very
high to electrically snip the lower end to the right length to tune
it. Another choke a quarter wave away would be necessary. All
doable, certainly, but ad-hoc.

Jeff,

You are treading down a well worn path.

There is a flaw in thinking that the shield of the coax below the bottom of your nominal dipole does not carry significant current on the outer surface. Whilst you are trying to account for the current distribution on the nominal dipole, you are ignoring the common mode current on the feedline.

The antenna will 'work' and you may be delightedm but if you expect that it will have very low VSWR based on formula dimensions, I think you will be dissapointed.

You might obtain better feedline decoupling by some form of common mode choke.

The failure of the sleeve to effectively decouple the dipole is the reason why several antennas don't work as thought. King gives some hints that the relative diameters of the conductors bears on operation.

I made a sleeve dipole cut for 375 MHz for listening to the Blue Angels in flight at NAS Miramar, c. 1992. It worked, but, heck, we could see them most of the time. I was in Coat Hanger Territory. By the way, the Blue Angles say very little in flight. :-(

This thread got me thinking. If three or four tuned radials were added, would this be a better approach? Yes, I realize it gets toward a lot of the standard commercial monopole antennas, with their 45-degree-down radials. I mention this because such radials could be added and still keep the builder in comfy Coat Hanger Territory -- that is, a very light, casual, cobbled-together antenna -- but something that works a bit better and helps the decoupling.

Frankly, I understand what it is to buy something and what it is to build something; I'd rather build. It keeps me off the street. :-)

Go with your sense of smell. The velocity factor of coax only applies
when the shield is positioned where it is designed to be. Let us know
how it fares.

A set of radials helps to decouple the feedline, in this case, you would place them a quarter wave below the bottom of the sleeve.

Ok, you have noted commercial implemenations of this idea... yes it is done. The quarter wave between the radials and the bottom of the sleeve carries significant current, ie it affects the pattern and gain.

And still, decoupling is not perfect, though much better.

Whilst the OP's design looks like it is simple, in my experience it is not. Whilst I have had a lot of success with coaxial dipoles where the sleeve was three times or more the diameter of the inner element and substantially air dielectric, I have had little success the the cheap and nasty approach of applying braid over a vinyl jacket and trying to adjust it for low common mode feed line impedance and low VSWR. I am not saying it is impossible, just not as easy as a ground plane!

Agreed. The feedline should be decoupled, which one can do by
wrapping a few turns into a coil and tied together with tie wraps.
Another method is a 1/4 wave decoupling sleeve further down the coax
cable.

>The antenna will 'work' and you may be delightedm but if you expect that
>it will have very low VSWR based on formula dimensions, I think you will
>be dissapointed.

Well, putting a 75 ohm antenna onto a 50 ohm system results in a
minimum VSWR of 1.5:1 assuming the coax is cut for some multiple of
1/2 wave electrical length. Also, most HT's are designed to tolerate
the fairly miserable VSWR presented by rubber ducky antennas and body
proximity.

In this case, the problem to be solved was rather mundane. A friend
was in the process of packing for a weekend camping trip with the
kids. His 13 year old daughter apparently had lost the rubber ducky
antenna from her Yaesu FT-60r. Rather than borrow an antenna, or
build an adapter kludge, he decides it's time for her to build an
antenna. They found some SMA cables, and proceeded to make a simple
coaxial sleeve dipole. However, there was some debate over the cut
length of the driven element because of the presence of coax
dielectric. I get a hasty email with the question and discover that I
really don't know the answer. So, I posted the question here. We'll
find out how it worked when they return.

Whether the home made antenna is optimized for best performance
doesn't seem to be important in this case. Any reasonable antenna is
better than a rubber ducky, so she should be fine (assuming she
doesn't lose another antenna).

>You might obtain better feedline decoupling by some form of common mode

Yes, that will help (as previously noted).

And the answer is not a simple as put by some. Particularly, if you had
in mind that the sleeve should be an electrical quarter wave to current
flowing on the outside so forming half of a centre fed dipole, and an
electrical quarter wave on the inside to form a quarter wave s/c stub,
the presence of high permittivity dielectric on the inside prevents
those both happening together... so you compromise, like discarding the
centre fed concept, tune the s/c stub for resonance (max decoupling, and
the sleeve will be less than a physical quarter wave), now tune the top
part of the dipole (it will be a bit longer than a physical quarter
wave) for lowest VSWR on the feedline.

> I get a hasty email with the question and discover that I

To some extent, everything 'works'. Just stripping a quarter wave of
shield off the end of a length of coax probably 'works' about as well.

>
> Whether the home made antenna is optimized for best performance

Indeed, it seems that for most modern hams, performance isn't an issue
or of interest.

I haven't. I also know that using the available RG-316 or RG-174 coax
cable is not going to yield optimum results. For a commercial
product, suitable for general consumption, such compromises are not a
great idea. However, for the purpose intended (short notice
replacement of a lost HT antenna suitable for a camping trip), in my
never humble opinion, is totally adequate. As long as it throw RF in
the correct direction, and doesn't cause the transmitter to shut down
from excessive VSWR, it should suffice.

>And the answer is not a simple as put by some.

With all due respect, the answer is NEVER as simple as the common
wisdom and practice. I just went through a similar mess in
rec.bicycles.tech, where I contended that many of the common design
practices found in todays bicycles are not sufficiently optimized.
When success is measured in milliseconds and profitability in tenths
of a penny, then good enough is never really good enough. Antennas
should all be silver painted, made from Litz wire, use Teflon
insulators, suspended air dielectric coax cable, and gold plated
connectors. That should squeeze the last 0.000001dB out of the
design. One can always make an antenna a little bit better.

However, I don't think the 13 year old will notice. Similarly, 90% of
the hams using a sleeve dipole coax antenna will notice. The real
question is "what is good enough". In this case, it's the ability of
a 13 year old to build an antenna on short notice, that works at least
better than the stock rubber ducky, with available parts, and probably
keep her out of the parents way as they load up the camper.

>Particularly, if you had
>in mind that the sleeve should be an electrical quarter wave to current

>flowing on the outside so forming half of a centre fed dipole, and an
>electrical quarter wave on the inside to form a quarter wave s/c stub,
>the presence of high permittivity dielectric on the inside prevents
>those both happening together...

Huh? I thought (err... guessed) that the dielectric only has an
effect if it were between the conductors. The grounded half of the
dipole formed by coax braid has the vinyl outer jacket forming a
dielectric. I presume this is what you consider to be a problem.
Worse, the jacket can be various grades (flooded, plenum, buriable)
with various dopings (UV proofing, gel filled). In general, it seems
to shorten the electrical wavelength. This is usually not a problem
because expanding the diameter of the coax braid, as it's folded back
over the shield, also mechanically shortens the braid. In the 2 or 3
such antennas I've built over the years, I've randomly shortened the
braid. What makes such arbitrary design decisions function is that
the dipole has a rather large operating bandwidth. One can be
incredibly sloppy and still end up with an acceptable antenna.

>so you compromise, like discarding the
>centre fed concept, tune the s/c stub for resonance (max decoupling, and
>the sleeve will be less than a physical quarter wave), now tune the top
>part of the dipole (it will be a bit longer than a physical quarter
>wave) for lowest VSWR on the feedline.

I must confess that I haven't bothered to try optimizing such an
antenna, while you obviously have made the attempt. What I usually do
with crude antennas is to attach one of several reflection coefficient
bridges in my pile or a directional coupler and some diode detectors,
sweep generator, and scope, and just play with the dimensions until it
works. Calculations, NEC models, and theory are great, but I prefer
to see the results on some test equipment. (For 2.4 and 5.7Ghz
antennas, I have a rather marginal test range and transfer standard,
which are suitable for estimating the gain of the antenna).

>> I get a hasty email with the question and discover that I
>> really don't know the answer. So, I posted the question here. We'll
>> find out how it worked when they return.
>
>To some extent, everything 'works'. Just stripping a quarter wave of
>shield off the end of a length of coax probably 'works' about as well.

That's probably what she ended up building. If she can talk into the
local repeaters, it's good enough. In this case, the 13 year old
antenna builder is probably not up to doing much more than measuring,
removing the outer jacket and peeling back the braid. I was going to
suggest adding a decoupling sleeve (using aluminum foil duct tape),
but decided that would be too much for a quick build. Maybe when they
return.

I forgot who rammed this down my throat when first got started in
engineering.... "The secret to engineering is to know when to stop

engineering and start building". It's a moving target, that has many implications, but my method is that when it meets the "suitability for purpose" criteria, you're done.

>> Whether the home made antenna is optimized for best performance
>> doesn't seem to be important in this case.
>
>Indeed, it seems that for most modern hams, performance isn't an issue
>or of interest.

That's also true for 90% of bicyclists. 90% of the bicycling public do not race their bicycles. Similarly, 90% of the hams probably are not optimizing their antennas and designs to what can theoretically be achieved. It doesn't take much to look at an existing design of literally anything, and think of a better way to do it. I do this all the time. (Former ladyfriend called it the engineering mentality and claimed it drove her nuts). Whether the average ham wants or needs that last dB squeezed out of the design is problematic. If I were doing moonbounce or microwave DX, where every fraction of a dB is important, I would certainly be into such optimizations. However, for yacking on the local repeaters, almost anything will work.

I'll probably steal a few of your ideas and comments in order to build a "better" coax cable dipole, if she returns with an interest in how it works, or how to make it better.

1838. 80 meter dipole

Newsgroup: rec.radio.amateur.antenna
Date: 2011-07-23 18:45:32 UTC
From: Eagle <none@thanx.wecum>
Message-ID: <j0f4sdick1@dont-email.me>
Source record: 4239

Hello,
I want to put up a center fed dipole for 75 meters. Trouble is, my lot
is not large enough to run the two legs without any bends.
My tower is in the center of my lot and is 60 feet at the peak, and is
40 feet to both ends of the lot.
What would the best solution be without using coils to "shorten" the
antenna?
I've had some luck by "dog legging" each leg of the dipole, but have
not gone past 200 watts power for fear of a arc.

Thanks,
73, W6IML

Hello Dave,

Having some bends in it (or a small vertical part) will result in
minor change, as you have sufficient straight length (your 80 ft lot).

You may need to increase the overall length somewhat and the input
impedance may reduce somewhat. If the ends run vertically and are
close to ground, length reduces mostly.

With kind regards,

Using only the wire, get as much of the middle as high as you can and put the last 20 or so feet of the antenna anywhere you can as high as you can get it. Most of the radiation of a dipole is from the center part of the antenna.

Try to keep the angle at the center as large as you can and not less than 90 to 120 degrees if possiable.

Eagle-

A quick calculation suggests you could put up a 144 foot inverted V
dipole with no other bends. You could elevate the ends or lower the
center to fit your antenna.

A Ham buddy 's son just got his General ticket, and asked for my assistance in making a surprise contact with his Dad for his first HF QSO. He had bought a nice 100W HF rig with an auto tuner, and an 40M-10M coax fed multi-band doublet antenna that was to be put in his attic initially. He lives about 100 miles from his Dad.

I thought this was really cool, so I said I would set the whole thing up. Suggested 80M early evening for that distance would be best bet. He told me the auto tuner would not tune the 40-10 antenna on 80M (5to1 SWR). He then asked (here is the magic part) what he could do in 1 hour to get the antenna to tune on 80M.

I told him to short the 40M loading coils, and add enough Home Depot wire to each end so that the auto tuner was happy. He had a 100' extension cord that he cut up and got the auto tuner happy <1.5 swr.

At QSO time he could hear neither his dad or myself, and we gave up. Not to be discouraged he removed the shorts and additional wire, the tuner provided a 5:1 swr, and he had a nice QSO with his dad. He also stated he heard a lot more signals than before.

Other than the obvious (he was mistaken in what he reported to me) any ideas as to what went wrong? I don't think he will ask for any more advice from me.

Which goes to show that power is not necessary for communications. (If
at 5:1, you are still getting half the power out into the ï¿½ther. Let's
call it 10:1 - that's still 30W out across 100 miles.) Nevermind the
smoke.

>Other than the obvious (he was mistaken in what he reported to me) any
>ideas as to what went wrong?

You mean the shorted coils and the extra wire? (Maybe he should have
turned it off, and then back on again - Oops, standard IT advice.)

Haven't a clue.

Propagation changed I bet. I strongly suspect the antenna
had nothing to do with it, and the extra wire and coils
bypassed was most likely the best system regardless of
the results seen when trying it.
It was most likely a fluke of nature, and I imagine
your antenna really was the best of the two.
If the band is kaput, nothing will work. 80m can get
really funky early in the evening. Have him try the longer
antenna a bit more at different times of day before discarding
it.. It should be fine. I have trouble seeing it being worse
than the shorter version with the less favorable match.

You forgot to offer burnt offerings to the radio propagation gods.

>I don't think he will ask for any more
>advice from me.

80 meters at 100 miles is in the range of the NVIS propagation. 25
miles is about the limit for 80m ground wave, and 300 miles is about
where sky wave starts. The problem with NVIS is that it's really
picky about the height of the antenna above the ground. I don't have
very much NVIS experience to offer any guaranteed suggestions on how
to make NVIS work reliably. I assume the kid will be talking to his
father regularly. My limited and unscientific tinkering empirically
determined that the NVIS horizontal antenna wire has to be fairly
close to the ground. A dipole that close to the ground has a fairly
low impedance. See "height above ground" section:
<http://www.w0ipl.net/ECom/NVIS/nvis.htm>
My guess(tm) is that with the antenna near the ground, most of the RF
goes straight up, which is what you want for NVIS, while an elevated
antenna delivers more RF towards the horizon. There are plenty of web
sites expounding on NVIS antenna and propagation worth reading. Tell
the kid what you think happened, but let him do the research and
tinkering.

> picky about the height of the antenna above the ground.

Not really. Just as long as the antenna can radiate upwards,
the height above ground is fairly non critical. IE: at dipole
at most any practical height will still be fairly decent at NVIS,
where as the usual vertical won't be. I've seen dipoles at
120+ feet still be good for NVIS on 75m. And they will be
better at long paths than the lower ones.

NVIS is sky wave, it's just high angle sky wave. I've often
seen good NVIS at 25 miles or even less. And often seen poor NVIS
at 25 miles. And it can flop back and forth in thirty minutes
time. Maybe quicker in some cases.
75/80 meters can get pretty squirrely in the early evening.
It's changing from the usual short daytime sky wave, to the
longer night sky wave. And you never really know what is
going to happen for sure. I've seen short distance NVIS
propagation go from strong to nil in thirty minutes time,
and visa versa. Lots of times, it will start out pretty good
early to short distances, then go kaput for shorter distances
for a while, maybe an hour or three, and then come back later
in the evenings. I see this a lot in solar cycle minimum years
in the winter. The MUF can actually drop below 4 mhz for periods
of time between various distances.
When that happens, all the close NVIS stations will be kaput,
and about all you hear is longer path stuff..
And then two hours later, it will come back, and you'll
hear the closer stations again. It generally gets more
stable as far as the F layer, the later it gets..
Usually by midnight or so, things are starting to get

fairly stable. But even that is no guarantee that
the short skip will be good.
Sometimes when the short NVIS skip goes south on 75,
we would jump down to 160m to be able to continue
talking. Then a couple of hours later when 75 came
back as far as short paths, we would go back.
Even on 160m, it's not unheard of to skip over people
at various times. There is a often a minimum skip zone
even on that band when using sky wave paths.

It's just like rolling the dice. I spend probably 85%
of my time operating on 80 and 40 using NVIS paths, so
pretty familiar with the usual antics the bands pull.
I'm almost certain that at the time he tested the first
longer antenna, the band was kaput to that distance,
and in the time it took him to redo the antenna and
get back on the radio, the propagation came back to
those short distances. Seen it a zillion times.. :/
I'm fairly sure the antenna wasn't the problem.
In our usual regional NVIS lingo, the band was boogered
up.. :| I think the antenna will be found to be innocent
once given a fair trial.

The modern explanation to modern hams is that an antenna tuner is there to keep the rig "happy". Modern folk are very busy people, they just don't have time for understanding, but personification of these inanimate things is apparently appealing.

Your anecodote demonstrates though how inadequate that explanation is, whether happy rig or happy ATU.

I understand your feeling that your pride has taken a bit of a dent. Well, part of the territory when predicting antennas eh!

Next thing, someone will market a happiness meter, an SWR meter rebadged and rescaled with a percentage happiness factor. Ultimately, the slow to respond rig manufacturers could incorporate a happiness meter under the covers, perhaps a range of LCD emoticons for those who don't want to think about percentage happiness. You could turn on a proper multimedia interaction, big groan for SWR>5 etc, big cheer for <1.2... bit like those terrible computer golf games "can't be too happy about that one!!!".

Owen

A dipole doesn't have to be without bends. Keep those bends fairly
less than 90 degrees at any one point and it should work okay. It
also doesn't have to be suspended exactly at the center feed point,
for instance, if the support isn't exactly 'centered' in your lot.
Lot's of possibilities. May not be the best in the world, or a
'classic' shape, but with a little 'fudging' here and there can
usually be made to 'fit' your available space.
- 'Doc

(Since that saying isn't literal, but a 'play on words', I doubt if
politics have much to do with the capitalizing. But then it could, if
you're of such a bent.)

Sorry, but that would be prior art:
<http://cybraphon.com/process/the-emotion-meter/>
<http://www.flickr.com/photos/cybraphon/3789780162/in/pool-917701@N24/>
<http://en.wikipedia.org/wiki/E-meter>
I worked on something similar for the audiophile industry, when I
invented an ambience and presence meter.

Personally, methinks the correct solution for such technical problems
is to virtualize everything and eliminate the antenna and radio:
<http://www.hamsphere.com>
<http://qsonet.com/programs.html>
With these, you can have all the frustration of DX, without the
expensive equipment and temperamental ionosphere.

Do try to have a better day (as measured on the emotion meter).

I tend to agree Mark, I don't have a lot of experience on 80M, but have been a Ham for 50 years. Propagation, the thing I know least about, is the logical answer. I will encourage him to keep trying the modified antenna at various times of day to get some better data. Hopefully, it will prove the better antenna, and the newbie will learn something in the process.

I was a Navy tech at a base in the Philippines in the early 1960s. Late one night (we were a 24-hour operation) with nothing much happening, one of the operators was in my shop, goofing with an ohmmeter. He picked it up and squeezed the leads, deflecting the needle some.

I don't know what possessed me but I told him to press the leads to his temples. It deflected a bit more. I explained that he had less resistance in his head than in his whole body, and declared him "smart" for that reason. Well, he got the joke immediately and we laughed about it. However, it didn't stop him from parading a goodly number of the watch section into my shop for Intelligence Testing. Oh, my!

The whole idea was to get the Kid on the air, and excited about Ham Radio, by making his first HF QSO with his Dad.

I think the learning will come later-he is a Patent Attorney-EE and Law degree. He impressed me Field Day when we were on an Island on a lake in South Carolina on 900 watt generator power. Had a lot of Impulse noise on RX even tho we were miles from power lines. Decided it was from the SMPS powering the Computer we were using for logging. The batteries on the Computer were good for ~1 hour, so we could not disconnect the SMPS for long.

While we were fretting over what to do, he butchered up a spent beer can, and enclosed the SMPS, dropped the noise considerably, I was impressed.

I hope he enjoys Ham Radio, in spite of my questionable advice.

Think of the experience in a different way. If ham radio propagation
were predictable and consistent, it would not be any fun. Just pickup
the microphone, set the controls, and talk to anyone in the world.
Kinda like a cell phone. It's the vaguarities of propagation, the
magic of sub-optimal antennas, and the mysteries of operation that
make ham radio fun. Considerable expense and effort, on the part of
major players and governments, to obtain reliable HF communications
has not been very successful over the years. Possibly "reliable HF"
is an oxymoron. Welcome the "kid" to the magic part of ham radio and
suggest that he adjust his expectations accordingly.

Incidentally, I usually carry a folded wad of aluminum foil for
improptu RFI/EMI shielding, probably because I don't drink beer.

FDC FD-880 Dual Band 136-174/400-480Mhz FM Radio
http://www.409shop.com/409shop_product.php?id=106081
Special features

Dual band,dual Freq.,dual display and dual standby
Working Mode:U-V,U-U,V-V can be set freely.
Band can be set freely on the same channel:VHF TX-UHF RX or UHF TX-
VHF RX.

PTT ID function;DTMF function
Offset Freq and Freq.shift direction can be set.
Keypad lock (Auto/Manual);Busy channel lockout

Water-proof;Wired clone function
Built-in FM radio;Led flashlight
3 displaying modes selectable(CH,FREQ,CH Name)

VOX function;Stopwatch function
Priority Scan;Multiple Scan modes;Adding channel scan
Emergency Alarm function;Wired clone function

Reverse freq.function
Multipe Step frequency(5/6.25/10/12.5/25/50/100KHz)
Charging directly from the power supply.You can also
charge your radio by connecting the supplied ac adapter directly to
your radio.

Technical specifications

Model NO. FD-880(Dual-band)

General Frequency Band VHF UHF
Frequency Range 136-174MHz 400-480MHz
Channel Capacity 128
Operating Voltage 7.2V DC ±15%
Antenna Impedance 50O
Channel Spacing 12.5kHz/25kHz
Working Temperature -30 ? - +60 ?
Frequency Stability ±2.5 ppm
Size (Without Antenna) 104(W)mmx62(L)mmx36mm(D)
Weight(With Battery) about 250g
Battery 1500 mAh(Li-ion)
Transmitter RF Pwr Output 5W/4W
Modulation Type F3E
Modulation Distortion < 5%(300-3000Hz)
Max Freq Deviation < 5kHz(1000Hz When 100%)
FM Noise <=-45dB

Receiver
Sensitivity (12Db SINAD) 0.16μV
Selectivity 55dB
Adjacent Channel Selecivity >=70dB
Noise Respond >=60dB
Communication Range 3-5km(Downtown),6-20km(In the Open Area)
FM Noise 30dB/40dB
Modulation Type 8K/16KF3E
Audio Power Output 500mW When Distortion Less Than 10%
Audio Distortion < 5%
Operating Bandwidth ±3.5kHz/3.75kHz
Standby Current < 12mA

Each Set PACKAGE CONTAIN

1 x FDC FD-880 (VHF136-174 / UHF 400-480Mhz Dual Band)
1 x 7.4v 1600mAh Li-ion Battery
1 x Dual band Antenna.
1 x Belt Clip.
1 x ENG Manual
1 x Wall Charger PSU (Provide PSU plug for your Country)
1 x 12V Car Charger Cable
1 x PTT Earpiece for free

1863. AB-952 Antenna Mast parts

Newsgroup: rec.radio.amateur.antenna
Date: 2011-07-28 13:44:24 UTC
From: Tom Horne <hornetd@gmail.com>
Message-ID: <f5bc99f5-0fea-4238-b217-cdbdf9be198a@r12g2000vbe.googlegroups.com>
Source record: 4164

Just in case anyone is also struggling with this problem I thought I would share how I worked it out. I have two AB-952 antenna masts. These are the thirty five foot masts that were used with a multiplexed tube radio system that provided the wonderful capacity of twenty two voice channels between major element headquarters of the Army in Korea. I have obtained an extension kit that extend the height to fifty foot. I was trying to assemble a second extension kit from parts because I couldn't find another complete extension kit.

Now to the problem. It is difficult to adapt antennas to the four inch tubes that make up the mast assembly. It is hard to find boom clamps that large. I found a source for the adapters that were used to support a different antenna than the one for which the mast was originally designed. Instead of the offset adapter that was used to support the corner reflector antenna this masts was originally designed for, I found the adapter for the dish antenna that was added to the system later. The dish adapter comes straight up out of the top of the mast and reduces in size to 2&1/4 inches outside diameter to accommodate the clamps that were on the dish reflector. That is well within the range of most of the boom to mast clamps that Hams use. I had seen these adapters only in manuals but I was picking up an extension kit, that Ben at Ontario Surplus helped me locate, from another surplus dealer and recognized the adapters that he had in stock. The dealers name is Tim Clark. He's in Lyndon, MD. He can be reached via [glengar comat verizon period net]. For those who do not recognize the term comat it is the "commercial and" that we all call at. If your into military stuff he has quite a lot of other GI stuff as well. My only relationship with Tim is that he has now supplied me with the parts to complete my AB-952 Mast assemblies at a very manageable cost after I was on the verge of giving up on ever completing them.

It took five years of patient searching but now both masts are complete. They allow me to hoist any of the smaller beams to fifty feet off the ground and to use the newly found adapters to attach a rotor or to directly attach a boom clamp and aim by turning the mast assembly from the ground using the strap wrench which is part of the basic mast accessory kit. These masts are really quite useful for any kind of field deployment such as field day, Boy Scout Jamboree on the air, public service events, and the list goes on.

I just thought that someone else might be working with these mast assemblies and could use help finding a good source of parts.

Well, the slogan is not quite what it seems. I was graduation from
Cal Poly Pomona back in the days when the skool slogan was "Learn By
Doing". The basic education plan was to get as much hands on
experience for the undergrads as possible. We modified the slogan to
"Learn by Destroying" which had more than a little truth to it. I
discovered quickly that the easiest way to understand how something
works is to (accidentally) break it, and then desperately attempt to
fix it before I'm discovered. It's a great way to learn, but does
tend to get rather expensive. A less drastic version is sometimes
called "sensitivity analysis" where one uses or installs a device in
some manner in which it was never intended to function in an attempt
to see how sensitive it is to installation and operation creativity.
This works well with antennas, where there are almost an infinite
number of ways to do it and still have it function.

We have some local hams that have never removed the screws from their
radios and looked inside. I often do this for them, while they
complain about warranty and loss of resale value. Tearing the radio
apart and giving them a tour of the guts (sometimes at radio club
meetings) is also fun (to watch them sweat).

You now have the unenviable task of acting as mentor to this new ham,
who apparently has the potential for more than minimal understanding
and knowledge. You may soon find yourself doing some furious reading
(or Googling) in order to just keep up with him. I've done this a few
times, where my usefulness eventually ends when the new ham tells me I
don't know anything. I just smile, and await the next victim.

1868. Automatic antenna tuners

Newsgroup: rec.radio.amateur.antenna
Date: 2011-07-31 20:30:17 UTC
From: ehoops <emmett.hoops@gmail.com>
Message-ID: <2bb452d8-e127-42a6-bbb0-a3888bf73e54@m18g2000vbl.googlegroups.com>
Source record: 4169

I'm getting back into radio after a 20 year absence. Back then, I had a QRP rig and a novice license; didn't worry too much about my antenna unless the SWR meter went past 2.5. What I did not have was an antenna tuner.

Now that I'm older and wiser, I realize an antenna tuner is probably a necessary thing to have. I'm putting up an 18' Hy-gain 5 band vertical antenna, leading to a Yaesu FT840 @ 100 watts. The matching ATT is not available, unless I'm willing to bid on E-bay for a hundred more than it cost new. (Believe me, I've tried this.) But I don't know what I should use. I know some tuners are designed for a specific rig.

Does anyone know what I should get? I'd really just like to turn on the radio, move to a frequency, turn on the ATT, and tap away. Help!

1869. Using speaker wire for a dipole

Firstly, is an ATU really necessary with your antenna. One of the selling points of these kind of antennas is that they are a fair match to 50 ohm line... though an ATU might overcome to some extent the narrow bandwidth on the lowest bands.

Next, there are a range of generic automatic ATUs, they fall broadly into those intended to go into a coaxial line and those intended to feed unbalanced loads like end fed wires, monopoles etc. The each have different matching ranges and applications.

Some of these generic auto ATUs can be interfaced to proprietary ATU interfaces on transceivers. Some transceiver support for ATUs is quite poor and might be construed as a marketing ploy, eg most Icom transceivers seem to abort a tune process after about 18s, so they do not integrate well with an ATU that might take 30s to find a match.

This lack of open interface, and flexible support is a problem. I attempted to design a protocol converter to properly integrate an SGC237 with an Icom radio, but I abandoned it because the SGC cannot be guaranteed to complete within 18s, and if it has to restart, it restarts from scratch and the same problem occurs. On the other hand, I was able to make a reliable protocol converter for a 'screwdriver' type ATU, as in the rare circumstance that the tune had not completed when the Icom aborted, the coil contact was closer to the desired point and in tests, always completed on the next attempt.

So, in my experience, Icoms work reliably with Icom ATUs, but have issues with some non-proprietary ATUs. This is why I say that ATU support is used as a marketing ploy.

> could put it to some good use.

If it is copper wire, it is more suitable than many things proposed for antenna conductor, though annealed copper is relatively low strength material.

Opinions vary, but wire insulation contributes little, if any, strength, but substantially increases wind resistance and mass, so it compromises the ability to withstand high winds.

The next question often asked in your situation is whether the speaker wire makes a good feedline. Contrary to popular belief, PVC insulated figure-8 cable is not a good feedline for HF antennas.

Owen

PS: hams universally ignore the guidance of NFPA 70 which makes recommendation on conductors for antennas.

I have an internal autotuner but one ham buddy uses an LDG auto tuner for
100 watts and he's happy with it. (He uses a high-power manual tuner if
he's using his amp.) http://www.ldgelectronics.com/

Some models, LDG or other, may be more suited to the FT-810; some radios
have a <TUNE> button that talks to the tuner via a custom cable, while
putting out Tune Power, about 10 watts. Otherwise, there should be no great
difficulty in you dialling up a tune power output and invoking the <TUNE>
finction on the tuner.

Good luck, OM

Yes, standards are expensive things and it is a frustration when researching.

Anyway, NFPA makes recommendation on the wires for ham antennas specifically, and it may be binding in some places.

I suspect the reason for ignoring it is that the advice is unaccepable to most hams.

That said, it does seem over the top in some areas, and is hardly comprehensive in its thinking. For example, the prescription for feedlines seems to not be aware of the existence and use of coax.

I guess it is these gaps that give critics the basis for arguing against the whole thing.

Anyway, in respect of antenna wires, it does not 'permit' annealled copper or other low strength materials, and it 'requires' a minimum conductor diameter of #14 for up to 150' span.

They may have had in mind the risk to persons and property where low strength conductor are broken in high wind and make contact with power lines.

Should work fine with the caveats of added weight from the insulation, etc.

Some years ago, there was a QST article written by a ham who built a 20
meter quad using insulated wire. He found that it changed the expected
resonance, IIRC downward. So you may have to play with the length a little
more than expected from the calculated lengths.

Message-ID: <QopZp.112808$8G4.95089@newsfe17.iad>
Source record: 4178

This topic is likely to spur a lot of discussion. For a while two of us
were using zip cord
which in itself is frequently used as speaker wire.

Mine was strung across and somewhat around the back yard to I could work 75m
and up with a tuner.
George, VE6VA surprised me when I noticed he had a feedling going out of his
shack -- it was cloth covered line cord! Both of us had lots of fun on the
bands.
I should add that my transmission line and both halves of the dipole were
made
from one piece of line cord/speaker wire -- I just brought the end of the
transmission
line into a plastic wire-tie, and fed the lines around the yard, using a
couple
tree branches and a small pole on the garage. The other dipole half was
just
long enough to reach the front of the house where it was then suspended
by a small lilac bush and a tall fir tree. End insulators were just bits of
scrap plastic and both ends were suspended with a long string of short
and medium pieces tied together! From experience I think that I can
generalize that you matter how much nylon line a ham buys, in time
it degenerates into a wide assortment of randomly short lengths, none
of which alone can serve any purpose!

After 50 plus years of hamming fun, I have come to the conclusion that
anything with a little metal in it will serve as an antenna if you hook it
up in the right manner. It has truly surprised me over the years just
how little antenna I had, and how far it was getting out.

Some antenna's will work better than others, and eventually every
ham, whose expectations eventually approch infinity will want to try
a 'better antenna'. Aside from collecting materials, and it doesn't
take much to make a dipole, once you know where you can string
your wires, it's easy to try a variety of antennas. In the long run
you will probably find that a half wave dipole will do the best,
and if you can drop the ends, changing it into an inverted-Vee
you will have near omnidirectional operation on the higher bands.

Antennas, discussed here have impedance, Jx+something or other, specific
lengths,
and so many rules that your life as a ham will make you miserable
when you dare approach the shack. Throw an arrow into the
air (throw an antenna into the air), suspend it here and there, and
then see if it works. If it does, Great! -- If it doesn't -- well, try

something else. Chances are you will have so much fun that
you postpone tidying up the knots, but some of those things
stay up for ever until their age approaches that of a typical
old fogie antenna fussy, Smith chart interpreter, know-it-
all hams, like most of us here

Antennas are funny people!

Get the wire up, have a ball!

Irv
VE6BP, Calgary

My favored gauges are 12 and 14. I took a dipole I modeled in EZNEC
(Evaluation Version) and changed from 12 gauge to 18 gauge. The behavior of
the antenna changed dramatically.

No, I'm kidding. EZNEC showed insignificant shifts in VSWR and gain at
optimum takeoff angle. You apparently face only mechanical issues. If the
wire parts when you pull it up, you'll need to connect it to a stout span
line.

I have two 20m dipoles hanging, one with a span line and one free-hanging.
They were both temporary ... last year.

Yes, I freely admit that I was a sucker who implemented that type of antenna system on the advice of mentors.

Since learning those j thingies that you deride, I have come to learn enough to quantify the sacrifice in performance.

Yes, it 'works', whatever that means!

One way to make sure newbies never challenge you is to lead them down the same misdirected paths as yourself in the hope that they never catch up.

Whilst there are those who glibly recite that "any antenna is better than no antenna at all", it is also true that you might work stations on any antenna, just you will work more on a better antenna.

I know that dumbing down the hobby is the fashionable trend, deride those who see ham radio as an essentially techical exploit as the new age ham is embarking on a social experience, just the connectivity is several orders of magnitude below those of most social network appliances. Whilst cutting edge hams are breaking DX records with things like WSPR at <0.5bps, kids are socialising on mobile phones at greater than 10Mbps.

When you take the passion for understanding the technology out of ham radio, it just doesn't compete.

Sal, there would be those who would chide you that such an antenna obviously wasn't big enough... in the sense that "if it didn't blow down last season, it wasn't big enough".

And we wonder why so many housing block have restictive covenants that are not ham friendly. We might just have bought that on ourselves to some extent.

I agree with Sal, LDG makes a good product. I have a Z11Pro2. It doesn't require any interface with the radio, it measures the incoming RF and antenna side SWR to know when to tune. It also latches the settings, so it stays set up even if I take power off of it (which I do when I'm not trying to tune it).

1884. Rawbolt size for standdoff bracketts + ali pole

To answer your question Pad,
Yes, 300 ohm feed line will do quite well for 2 meters at 50 watts IF it's
made correctly and you have a good match.

Kevin, WB5RUE

Quoted correctly or not it's still accurate.

They say it can be done... Not my choice though. I prefer simple 1/4 wave ground planes as simple emergency or temporary antennas.
IE: a 1/4 wave ground plane can be made with five pieces of wire and an SO-239 connector. Or a telescoping whip that can extend that far, and four pieces of stiff wire for radials, which would be bent out at about 45 degrees.
I think the 1/4 wave ground plane will be a better decoupled antenna vs the usual J-pole, assuming no other decoupling methods are applied.
Another advantage is no matching schemes are required.

Are you saying the electrical code is sort of like the pirate code? more guidelines than actual requirements?

I think the way that hams can rationalize it is that most wire antennas (particularly those made with fine wire) are, by their nature, "temporary installations". The finer the wire, the more temporary.

You have a point Mark. I agree that a simple 1/4 wave groundplane is more
study and very easy to make using an so-239 and some piano wire. Steel wire
can be soldered right into the back, four bolts with nuts and four more
peaces of wire around 19" long with a bit of a downward bend and you have a
very good antenna.

I think that 12mm will be just fine. I'm in the US and some of your terminology is a bit obscure to me, in particular "rawbolts" and "T+K standoff". But I'm bilingual, I speak inches and meters so bolts of that size should hold that short of mast up just fine if the standoffs are up to the task.

It won't smoke if the antenna is tuned, but you could get burned from
the rig or mic.

Those antennas need to have serious choking done on the feedline, at
least 2 a quarter wave apart on the feed just before the antenna.

Doing so helps make the pattern more like what is expected and reduces
hot radio and mic issues.

Examples 7 and 8 in the catenary calculator at
http://vk1od.net/calc/awcc/awcc.htm use #14 and #10 HDC. Readers can
explore the survivability of wind and ice with the calculator.

If I model a 45m simple span of #14 HDC at the lowest wind speeds
applicable to the design of structures in this jurisdiction, using the
mandated safety factor, the minimum sag is about 5% of span, about as
large as it typically practical for such a span.

NFPA 70 does not apply in VK, though there are standards that apply and
the answer comes up pretty much the same, just there is more freedom in
engineering shorter spans.

Thanks John, You've already guessed I think that I'm in the UK where we seem to mix up units of everything quite happily millimetres', inch's, pints, litres, Km, miles

Anyway back on topic the T+K bracketts are just the shape T at the top and K shape at the bottom. One thing I forgot to add was the wall type it's a 'breeze block' construction or cemet block I think that's a cinder block in the US, and the wall has a filled cavity.

It's Rawlbolt. It is a brand of expanding anchor.

I used 10mm resin anchors for a similar installation into brick, they have
the advantage of being less likely to crack the brick as compared to
expanding/rawl bolts. Breeze block is a dubious material, depending on it's
strength it may or may not be ok. If it is a dense concrete block you should
be ok, but I'd recommend resin type anchors anyway. I got mine from screwfix.

It is small diameter, high resistivity material. If it is magnetic, even worse.

I depends on its length, and the current flowing.

The article http://vk1od.net/antenna/conductors/loss.htm includes an example of 316 SS MIG wire.

It is great for stealth antennas, actually doubly so, because not only is it hard to see, it is hard to hear.

At one time I was working JA from yhe UK using a long wire (about 40m) of 30 swg and 100w. It didn't blow down. however it was only up for a week as a stealth ant. currently my long wire is 1mm enameled wire, to be less vu=isibly intrusive (and at current copper prices cheaper) than the recommended 14 swg (12 awg).

This replaces one which failed a couple of years ago constructed with thin insulated 5A lighting flex not much more than bell wire that had been up nearly 30 years.

It's better using a non optimal stealth ant than none at all!

I'd use copper wire vs the steel or piano wire. They would work,
but I think the copper would be a better conductor. Steel in
particular is not too good. Also copper is a lot easier to solder to.
If you use solid wire of say 12 or 14 gauge, it's stiff enough to
stand up straight, but flexible enough to be bent and hold it's
shape.
If you are going to hang the antenna from something, you can use the
inner conductor of coax as the radiator, "shield stripped back 19
inches" and attach wire radials to the shield. All you have to do is
hang it up, and then bend out the radials at about 45 degrees, and you
are ready to become radioactive.

For a deluxe version, shave off the covering of the braid a 1/4 wave
below the radials at the feed point and add a second set of radials
to the braid.
That version would be well decoupled. Would blow most J poles out of
the water I suspect if you want to concentrate on the horizon, vs up
at some peculiar angle which is fairly useless for VHF/UHF.
Decoupling of the feed line is more important than radiator gain on
those bands. IE: a 1/4 GP can often outperform a 1/2 wave vertical if
the 1/2 wave has little or no decoupling. Which is the case for most
1/2 wave J poles.

NFPA (according to what you posted) requires heavier gauge wire for
transmitting than for receiving. Transmitting makes the wire weigh more?

Funnily enough I was just looking into chemical (resin) fixings - do you have a link for the screwfix anchors you used ?

I have in the past used rawbolt's and indeed split the wall, well the ones near the top, a low thump as I tightened them up. They seemed ok with no problem afterwards with a 2m 10XY and a 88ele 70cm beams (this was my mum & dads house!)

It's worth noting that you don't actually need four radials. Two radials (on opposite sides of the feedpoint, bent down at around 45 degrees) will produce a perfectly satisfactory ground-plane. The patterns of 2- and 4-radial ground plane antennas are almost indistinguishable. A 4-radial antenna may *look* as if it would produce a much more circular pattern than a 2-radial antenna, but this doesn't turn out to actually be the case.

I'm in a 1960s neighborhood. If anybody bitches about
antennas (nothing, yet), I will invite their attention to the old-fashioned
utility poles & wires that decorate (?) the streets. A few blocks out and a
few years later, they undergrounded the utilities.

This got me thinking. (Dangerous, yes, but I occasionally risk it.)

Since a normal dipole has current max near the center, is there more localized heating (I-squared-R) nearer the feed point? Seems like it ought to be. Can you overheat a small wire and make it fail there by melting?????

No, I don't want to try it. I'm hoping somebody knows. Exciting story even better.

That's true as far as the pattern. But.. The more radials you
use, the better the decoupling from the feed line. Most of my
1/4 wave GP's actually use 6-8 radials. I've done tests, and
it does make a difference. But for casual use, what you say is
true. Only two radials are required to get a pretty good omni
pattern. Or one, if vertical.. But then you might as well call
it a 1/2 wave vertical instead of a ground plane.
And you will then require some kind of decoupling scheme below
the vertical for optimum results. I prefer radial sets, cones, etc
vs feed line chokes.

Be aware that the National Electric Code (NEC); that is enforced as law in many jurisdictions; forbids the use of wire that small for aerials of radio stations. The NEC specifically requires that size fourteen American Wire Gauge be the minimum size that is used.

In point of fact you are unlikely to ever get inspected unless some neighbor is raising a stink about your antenna. The danger is that in the event of a physical failure of the antenna that brings harm to anyone or anything, the use of non code compliant size wire will shift all blame on to you. That could include a trespassing neighbor kid yanking on your coax lead in and being burned before you realized that the antenna was in direct contact with him because the wire of the antenna that was supporting the coax had failed. The reason that you might be blamed for something that at first blush appears to be outrageous conduct on the kids part is based on the idea that anything like that which is not sufficiently guarded so as to prevent that kind of occurrence is considered to be an attractive nuisance in the eyes of the law.

If the wire is supported on a messenger that has at least the breaking strength of #14 AWG wire the reasonableness standard should serve as an effective shield against that particular approach in a law suit. Be aware that in electrical parlance, which is what the code is written in, messenger supported means that it is continuously supported by another means. It does not mean that it is suspended from some stronger support at it's ends. To be messenger supported the entire weight and the catenary strain of the support system would have to be born entirely by a means other than the undersized conductor itself.

I am not a lawyer nor do I play one on local cable access television. If you need advice about the most likely legal affects of an injury that is caused by your amateur radio equipment you might want to patronize a law schools legal clinic. The Professors that supervise such clinics love questions like this because they take a fair amount of effort to answer well. What you end up with is really high quality advice prepared under the supervision of some of the best legal minds that a person of ordinary means could ever get access to.

I've quoted the sections of the NEC which are applicable to antenna conductor size below. Be aware that the NEC contains many more provisions covering amateur radio stations specifically. It is worth

your time to obtain the use of the edition of the NEC that is adopted for enforcement in your community and check your installation against the provisions of the code.

Tom Horne, W3TDH

"ARTICLE 810 Radio and Television Equipment
I. General
810.1 Scope.
This article covers antenna systems for radio and television receiving equipment, amateur radio transmitting and receiving equipment, and certain features of transmitter safety. This article covers antennas such as multi-element, vertical rod, and dish, and also covers the wiring and cabling that connects them to equipment.

810.11 Material.
Antennas and lead-in conductors shall be of hard-drawn copper, bronze, aluminum alloy, copper-clad steel, or other high-strength, corrosion-resistant material.
Exception: Soft-drawn or medium-drawn copper shall be permitted for lead-in conductors where the maximum span between points of support is less than 11 m (35 ft).

810.12 Supports.
Outdoor antennas and lead-in conductors shall be securely supported. The antennas or lead-in conductors shall not be attached to the electric service mast. They shall not be attached to poles or similar structures carrying open electric light or power wires or trolley wires of over 250 volts between conductors. Insulators supporting the antenna conductors shall have sufficient mechanical strength to safely support the conductors. Lead-in conductors shall be securely attached to the antennas.

810.13 Avoidance of Contacts with Conductors of Other Systems.
Outdoor antennas and lead-in conductors from an antenna to a building shall not cross over open conductors of electric light or power circuits and shall be kept well away from all such circuits so as to avoid the possibility of accidental contact. Where proximity to open electric light or power service conductors of less than 250 volts between conductors cannot be avoided, the installation shall be such as to provide a clearance of at least 600 mm (2 ft).

Where practicable, antenna conductors shall be installed so as not to cross under open electric light or power conductors.

[One of the leading causes of electrical shock and electrocution, according to statistical reports, is the accidental contact of radio, television, and amateur radio transmitting and receiving antennas and equipment with light or power conductors. Extreme caution should therefore be exercised during this type of installation, and periodic visual inspections should be conducted thereafter.] This is explanatory

material from the NEC Handbook and not part of the NEC.

810.14 Splices.
Splices and joints in antenna spans shall be made mechanically secure with approved splicing devices or by such other means as will not appreciably weaken the conductors.

[Conductor spans from antennas should be of sufficient size and strength to maintain clearances and avoid possible contact with light or power conductors. Splices and joints should be made with approved connectors or other means that provide sufficient mechanical strength so that conductors are not weakened appreciably, a condition that could cause them to break and come into contact with higher-voltage conductors.]
This is explanatory material from the NEC Handbook and not part of the NEC.

810.15 Grounding.
Masts and metal structures supporting antennas shall be grounded in accordance with 810.21.

810.52 Size of Antenna.
Antenna conductors for transmitting and receiving stations shall be of a size not less than given in Table 810.52.

Table 810.52 Size of Amateur Station Outdoor Antenna Conductors
Material Minimum Size of Conductors (AWG)
Where Maximum Open Span Length Is
Less Than 45 m (150 ft) Over 45 m (150 ft)
Hard-drawn copper 14 10
Copper-clad steel, bronze, or other high-strength material
14 12

810.53 Size of Lead-In Conductors.
Lead-in conductors for transmitting stations shall, for various maximum span lengths, be of a size at least as great as that of conductors for antennas as specified in 810.52." Copyright 2002 the National Fire Protection Association.

Yup. The amount of current that would do that is called the "Fuse
Current" which can be dramatically large. Example, wirewrap wire's
fuse current is slightly more than 10 Amps.

And of course, there are hams out there who consider the NEC, as applied to
antennas on their own property, to be an irrelevant government overreach.

Naturally, that is not my opinion :)

Come on, Guys!

While it's a great idea to follow every official code and reccomendation, and that no one in their "right mind" would ever consider anything less than the lowest gauge copperweld wire for their antenna, the original question is answerable by "Yes, you can make a serviceable antenna out of speaker wire."

Will it stay up as long as a Copperweld antenna held in place by1/4 inch thick 100 percent nylon rope?

No it won't.

But it will work. Surprisingly well, in fact.

Let the new guys learn, and throw up antennas that work. As they have to put up a new one every so often, they will eventually learn about more long lasting antennas, as well as ones that might have a better pattern, and other effects that bear on performance.

But the idea that hams are responsible for restrictive covenents (in reality, Cable television is more responsible for antenna covenants than anything else) or that the choice of speaker wire is going to electrocute the neighbors is doing a disservice to the new guys and gals.

I can say this with some conviction because I was one of those noobs once, and nearly didn't even get on HF because with all the input, I gave up on putting up an antenna because nothing was good enough. I didn't have enough space, I didn't have enough height. There just wasn't any use in getting on the low bands. I needed a separate antenna for every band because ladder line was awful and traps were bad and every other option was awful except for some idealized correct antenna, coax fed, at the proper height.

I have found that the safest option is to not ever put up any antenna whatsoever, Tom. It's just too dangerous, and gives us unneeded exposure.

Can you ensure that an antenna that is installed to the code specifications, will not fall down?

Will your code spec prevent you from incurring liability if a wire antenna falls down and electrocutes a neighbor?

The answer to both questions is "no", BTW.

I find that this entire discussion is pretty amazing when compared to the original question.

As opposed to electrical code and liability admonitions, perhaps a good answer is:

"Yes, you can make an adequate antenna from speaker wire. There might be better options, though."

I've found that when I attempt to speak the language, I'm pretty well treated.

Now there is the possibility that they just find it amusing and charming, because I took both French and Spanish, and in conversation I can slip between both languages inadvertently.

Usually when I note that I "Parlez poco Francaise" they start smiling....

As for New York, I haven't had much trouble there, but then I give back what I get. Most seem to actually like some attitude. Go figure!

Thanks, looks cheaper than Screwfix. Did you use a normal 'frame' with the resin, I think some of them need a stronger frame because of the viscous nature of the resin. Looking at the spec this resin is really strong stuff I didn't realise how strong it was - about 2800Kg tensile strength on a 10mm bolt !....

My present HF antenna is a piece of 4-conductor ribbon cable, with 60 feet of each outside conductor pulled off to make a 120 foot dipole, the rest of the cable being used as a feedline to a balun and thence to a tuner. Is it ideal? No. But it's good enough to work 45 states so far on 75m, a few dozen DX contacts on 20 and 40m, etc. Plus, it's nearly invisible against the side of the house.

During field day, I used a homemade doublet fed with 450 ohm ladder line to the same tuner, remotely mounted in a waterproof box, I was able to work 15m and 80m on the same antenna, made a few hundred contacts. Eventually (when the leaves fall) I plan to replace the ribbon cable dipole with the doublet and the remote tuner on some tall trees in the backyard.

Very simply, yes, it can be used for making antennas. If it's strong enough to hold up it's own weight, and that of the feed line without stretching unreasonably, then it should do fine. What happens if it stretches? You shorten it. I think I'd try a larger size for 160 meters and maybe 80 meters, but if it can stand the weight and the weather, why not?

I have a Heath HM-2102 VHF SWR power meter 50-160 MHz
0-25 and 0-250 watts. Excellent condition.

I'm *asking* $40 plus shipping.

It can be viewed at:

http://home.comcast.net/~hsknoll/site/?/photos/&PHPSESSID=29ec62ea0bf1fe4d25e318b011cf0bbf

or

If you hang on to it a little longer it will be a 'classic' and you
can ask more for it!

In actuality, things like that are available at a lot of ham flea
markets, and in some cases, hams will give you things like that
just because they are 'real' hams.

Right.

But I would like to say that it isn't at all that the information is wrong. In fact, the experts are generally 100 percent right. And that is where some of the problems are.

A noob comes in, and gets 3 different answers, and becomes hopelessly confused because they would seem to contradict each other. They don't really know how to figure it out.

It isn't confined to this group. Another group I'm in where I am a bit of an expert, Amateur telescope making, some times suffers from the same thing.

My point is that I'm not trying to chide the experts. After all, it's not very graceful to bust peoples chops when they take the time to answer a question. I's more begging them to realize that I'm a bit of an idiot, and easily confused!

Yes.

I have properly-built 6m jpole which terminates in my shack. If I
disconnect the coax from the 6m rig, the connector center pin fits nicely
into the LONG WIRE terminal on my HF tuner. Electrically, the antenna is
merely a 13' hunk of metal, untuned as far as HF is concerned, except after
a little tuner knobulation. It's not the equal of a 'proper" antenna, but
it works.

SS is a terrible conductor?

I've seen copper clad MIG wire

The real issue is either you're putting that antenna up for the ages, in which case the NEC (aka NFPA 70) rules are a good sizing guideline; or, you're putting it up expecting it to fall down sooner or later, in which case you might as use whatever wire is convenient. For a lot of folks, buying a 500 foot spool of solid AWG14 wire at the hardware store is a good compromise.

The real issue is paying attention to "what happens when the wire breaks" so that you don't wind up inadvertently connecting the 14.4kV MV distribution line to your hand via the feedline and rig.

An interesting observation. You'd have to go look at the history of
that article in the code to find out why. It's not impossible that they

were following standard commercial installation practice/recommendations back in the day, and it was "acceptable power loss" related. (the wire sizing for AC branch circuits is based on tolerating a 2% voltage drop, not overheating of the conductor)

Fusing current is remarkably high for small conductors in free air, even
for 100% duty cycle.

AWG30 (0.01" diameter) = about 10 Amps (Preece equation)

Scales as 1.5 power..
so, going to AWG 20 (.0316") -> about 50 amps..

Considering an inverted V dipole with feedpoint Z of 50 ohms, at 1kW,
the current is about 5 amps...

So running that legal limit amp with a brick on the key to your AWG30
stealth antenna won't melt it. (it probably will get pretty warm.. and
corona at the ends might be spectacular)

I was thinking more of local codes or enforcement. After all, the local "Authority Having Jurisdiction" (AHJ in code-speak) can and does override the NEC all the time.

There are also a whole lot of other "installations of a temporary nature" in the code: check out the sections about theatrical and motion picture filming. They allow substantially higher currents for a given size wire, on the not unreasonable basis that they're being operated under the (hopefully) continuous supervision of qualified personnel.

1949. HF Antenna Options: Need Advice

Newsgroup: rec.radio.amateur.antenna
Date: 2011-08-06 19:51:28 UTC
From: Todd Carney <carneytf@gmail.com>
Message-ID: <5d1f4008-b1e8-4594-89f4-b6a9be033483@y8g2000prd.googlegroups.com>
Source record: 4100

I'm a neophyte here, but I've done quite a bit of reading on antenna characteristics and design. Still, I'd appreciate some advice from the more knowledgeable (that's pretty much anybody here).

1. I have pretty limited options for a serviceable antenna for, say, 40 to 10 meters. Right now, I am interested in CW only using QRP rigs (homebrew) for DX QSO's.

2. I want to limit the visual impact, so unless you advise strongly in favor of them I want to avoid verticals. I don't have code or covenant restrictions, but I do have a wife.

3. Here's the physical situation: My suburban property has two houses on it but no real trees I could use as anchor points. However, from peak of the big house to that of the guest house I can get about 96 feet. The big-house peak is about 25 feet high and the guest house about 13. For visual purposes, I'd like to use as thin a wire as possible.

4. Here's my idea: an end-fed wire with traps for multi-band use. I don't see how I could use a center-fed dipole unless the feeder came back parallel (right next to) along one leg of the dipole. In other words, I can't feed at perpendicularly. For a variety of reasons, the azimuth of a wire line between the two houses would be about 25 degrees/205 degrees.

So . . . what do you think? What kind of performance do you think I could expect from this setup?

Many thanks! ---Todd

It was a lot like that in Germany in the 80's .I was stationed there
for 3 years and found if you get out of the "GI Towns" and went to the
smaller villages and towns outside of the bases they treated you like
gold.Of course I guess that's like anywhere else you get out of the
big cities and people are a more laid back .

MFJ claims that some of its products indicate PEP on SSB telephony, and some of the claims are plainly fraud.

In my experience, if the instrument does not use an active 'sample and hold' amplifier, it does not work adequately.

In the MFJ949E tuner, the PCB has provision for a single transistor amplifier, which if fitted, works passably... but they do not populate the board with the 20c worth of parts needed.

The good news is that the MFJ868 does have an active PEP amplifier, it looks a similar circuit to that in my AL80B which does work quite well. I have not checked the circuit in detail, nor the time constants involved, but this has a chance of working and working well.

> Is it really a true peak reading meter?

Well, of the MFJ949E, MFJ says "Lets you easily read SWR, true peak forward and average reflected power simultaneously on 300 Watt or 30 Watt ranges", and let me assure you that their "true peak forward" is a fraud... so this claim questions MFJ's credibility.

Don't trust any advertising claim with the word "true" in it.

BTW, the reflected meter in the '949E does not read average power of SSB telephony either, both meters can read the average power of an unmodulated wave.

Sellers make extravagant claims to a tame market that mostly doesn't understand the technical side.

Try an off-center fed dipole (OCF).

Here's what I use:
http://www.wcerc.org/Projects/ocf_dipole.asp

Here's the balun I use:
http://www.balundesigns.com/servlet/the-75/OCF-balun-4-cln-1/Detail

I am a QRP CW operator with no trees on my property. I run a Small
Wonder Lab SW-40 (1.5 watts) and a Yaesu FT-817 at 2.5 watts. The

balun is tied to a PVC vent pipe on my roof, about 25 feet in the air. The long end of the antenna goes to my shed and terminates about 15 feet above ground. The short end runs to my garage and terminates about 12 feet above ground.

The antenna loads on 80 but the bandwidth is very small. Works fine on 40 -- with my QRP rigs, I work into Europe, S America, Caribbean, Canada, all over US, occasionall into South Pacific.

Here is a commercially available OCF dipole:

http://hamcall.net/7bandocf.html

```
Posted-By: auto-faq 3.3.2 beta (PGPMoose V2.0, Perl 5.005)
Archive-name: radio/ham-radio/recruitment
Revision: 1.2 2009/11/25 14:41:01
Posting-Frequency: posted monthly
URL: http://www.faqs.org/faqs/radio/personal-intro/

Changes followed by "|".

The rec.radio.info newsgroup, first established in 1993, has been
recently revived by an active moderation team. We are currently seeking
suitable information, FAQ, and bulletin articles from the entire
rec.radio.* newsgroup hierarchy for simultaneous cross-posting to our
newsgroup.

We are seeking a replacement maintainer for the following information
bulletin formerly posted to rec.radio.amateur.* (and currently archived
at http://www.faqs.org/faqs/radio/personal-intro/ ):

radio/personal-intro
Subject: Guide to the rec.radio Newsgroups
Maintainer: jeffreyh@Hawaii.Edu (Jeffrey Herman)
Last Posted: 9 Nov 2001 06:18:17 GMT
Posting-Frequency: 15th of each month

One significant omission, requiring immediate updates, for this article |
is that it does not mention newer amateur radio newsgroups created since |
it was written, including: |

rec.radio.amateur.antenna |
rec.radio.amateur.boatanchors |
rec.radio.amateur.dx |
rec.radio.amateur.equipment |
rec.radio.amateur.homebrew |
rec.radio.amateur.moderated |
rec.radio.amateur.space |

We are willing to provide any technical support necessary to get this
article updated and automatically posted again at a regular interval.
This would include establishing contact with the original maintainer for
any necessary permissions. We would prefer to seek a new, dedicated
maintainer at this time, rather than start auto-posting the original
article ourselves.

For more information about our newsgroup, see:
```

http://www.panix.com/~rram/usenet/rri/index.html

Please direct any comments, questions, or criticisms to
rec-radio-info-request@panix.com.

I'm inclined toward OCF also. I ran one for a while, which worked out well because I could run the feed down to the shack window right at the short side of the thing. I'd suggest a tuner as well. They do tune okay, but the tuner extends the useable frequencies. Also, my antenna was marginal at 20 meters. OCF isn't the "ideal" antenna, but you could do a lot worse.

Source record: 4111

Only if you modify the yagi to resonate on 2 metres.
Here is a link that will help you:

http://www.arrl.org/files/file/Technology/tis/info/pdf/9611034.pdf

The article on the TV to 2m conversion is on the ARRL Technical Info site:

http://www.arrl.org/tis/info/Yagi-V.html

It is a copy of the original article from QST magazine, and is only
available to ARRL members from that source.

Agreed. Forgot to mention that I use a tuner with mine.

I have an old ICOM IC-729 with the companion AT-150 tuner.

1962. Vertical on metal patio cover

Newsgroup: rec.radio.amateur.antenna
Date: 2011-08-08 02:42:03 UTC
From: Wayne <mygarbagecan@verizon.net>
Message-ID: <almarsoft.1804041638909588266@news.eternal-september.org>
Source record: 4113

A while back I asked about experiences on the group with verticals on metal patio covers. Today I had a chance to run an experiment that turned out fine. There is a lot of conduit above the cover for fan, 2 outlets, and 6 lights. I used a mobile antenna roof rack mount on a section of conduit and mounted an Outbacker mobile antenna.

Twenty meters was the only band tryed, and results were OK. Best of all, the antenna received approval by "she who approves things". Next step is to put up a longer radiator without loading coils.

Yes, it will work. I just tried it with my HT. From southeast of San Diego, I raised a repeater on Mt. Santiago, Orange County, with a 75-ohm directional VHF TV antenna and a half-watt signal. Santiago is 70 miles away. Disclaimer: My location, on a small hill with a generally clear view toward the North, gives me an advantage.

Then, I put the analyzer on that antenna and I was surprised to find the 2m VSWR was 3.1:1, worst case. Losses through about 50' of cable from here to the antenna no doubt helped my VSWR number.

There is some risk of using it with a high-power rig if the rig isn't internally protected against operating into an excessive VSWR. Most are.

Start at a modest power and see what happens. That's what a lot of hamming involves ... try it and see. Smoke is possible but not common.

My 15 year old son is exploring shortwave radio, and has purchased a Realistic DX-394a. We're experimenting with various antenna configurations, now trying an inverted L. The layout so far can be seen at:

http://i258.photobucket.com/albums/hh242/winwinsit/antenna2.jpg

So, a single strand wire crosses the yard at a height of about 14-18 feet, stretched east-west, insulated at each end, and another length of wire connected to it drops to below a window, then passes through the wall and to the Hi-Z antenna input. (The diagram shows a lightning arrestor, but that isn't attached yet.)

But it seems to offer little or no advantage over the little telescoping antenna. In fact, the best reception is when we touch the antenna lead wire to the telescoping antenna. Do you suggest:

1) an antenna tuner?

2) coaxial cable running from the radio (Lo-Z input) to the end of the 75 foot run?

3) a north-south run?

4) a completely different configuration?

5) anything else?

St. Bernadette says,
"And now as I stand Here in the Heavens with The
Beloved Mother, with The Divine Holy Trinity, I am
allowed to speak to you to help you come Here. The
purpose of this Great Miracle is to teach you God's
Way, to give you firsthand, His Wisdom, His Truths.
So, I repeat to you what The Heavenly Mother once
said to me: 'Walk in modesty, walk in purity, walk
in obedience, walk in trusting God alone, walk in a true
love and not an imaginary one."

REVELATION DELIVERED THROUGH FRANCES M. KLUG
ON MARCH 18,1972- EVENING

SAINT BERNADETTE

"My beloved children, I am Saint Bernadette
and I come to you on this night for a special reason.
When Our Lady appeared to me when I was in the world,
She stressed purity, She stressed modesty, She stressed
truth and She stressed self-discipline, and She stressed
doing all things God's Way and in His Will. And now,
as I come to you on this night through a child as you,
time is repeated, and there are similarities here as I
speak to you.

Many men said that my Visions could not be true.
I knew they were, for you see, when Our Lady spoke
to me, She spoke of the Divine Beauty of Heaven. And
I knew, the manner in which She spoke, the feeling I
had when She spoke, the sight I saw with my eyes,
could not have been imagination nor man. I carried the
beauty of this all through my life and when my physical
time was about to end, I did not feel pride in having
seen what I had, but I felt a great desire to do all I
could to help other men.

And now as I stand Here in the Heavens with The
Beloved Mother, with The Divine Holy Trinity, I am
allowed to speak to you to help you come Here. The
purpose of this Great Miracle is to teach you God's
Way, to give you firsthand, His Wisdom, His Truths.
So, I repeat to you what The Heavenly Mother once
said to me: 'Walk in modesty, walk in purity, walk
in obedience, walk in trusting God alone, walk in a true
love and not an imaginary one.'

I bless you with God's Love and I say, 'Hold tight
to the Holy Rosary every day, and when you do your
Heavenly Mother loves you.' So be it."

I found the manuals and the schematic online but I still need to engage in guesswork. Work with me.

You said best reception is obtained by touching your lead-in to the telescoping antenna. Would you believe there is one and only one component betweent the ANT HI-Z jack and the termination of the telescoping antenna? it's a15 pF coupling capacitor. I guess it's bad .

Its reference designation is C179. There is another component in the circuit, a 100K static drain resistor, R190, connected to ground. Resistors rarely short out, so I won't guess that; besides, if it were to short, it would hamper reception with the telescoping whip.

Connecting your outside antenna to the telecoping whip with a clip lead may be OK, now and forever. I'd like to see you do it through a 15 pF capacitor, if possible. This project/repair may end here.

If you want to proceded with troubleshooting, connect your antenna to the ANT HI-Z jack. Open the case and move the body of the ANT HI-Z jack while listening. Wiggle it gently. The solder joint to the PC board may have cracked. I've seen about six of these failures with consumer equipment. Sometimes an easy fix, sometimes a PITA.

If you can locate the junction of C179 and R190, touch your antenna lead to that point instead, still while listening. There is no voltage there and you can't be hurt. (It's like touching the telescoping whip, actually.) R190 is a few milimeters in from the ANT HI-Z jack on top of the board. It's an easy reach. I can't tell you which end is which. If you touch the ground end first, nothing will happen, if you touch the correct end first (and the ANT HI-Z jack is bad) you will hear signals. If you don't hear them, it's probably C179 that's bad.

Maybe I've gone too fast and confused you. Read it again and/or get back to me.

I guess one other option is to try your other connection for an external antenna, labeled "ANT LO-Z". What does that do for ya? If you were to change your antenna to a coaxial-fed dipole, the ANT LO-Z would probably be a good match at most frequencies. If you are already "experimenting with various antenna configurations," you ought to try that one, too. The attenator switch, ATT 0dB - 20dB, is in-line with that path; work the switch a few times to be sure it's free of corrosion enough for good contacts.

Feedback to me would be nice. A Nobel Prize would be a bonus.

I would suspect that if you simply touched the same place with your
finger (no antenna then either) you would get "the best reception."

>Do you suggest:
>
>1) an antenna tuner?

Very much suggested, yes.

>2) coaxial cable running from the radio (Lo-Z input) to the end of the
>75 foot run?

A move in this direction would foster more options when you experiment
with other antennas.

Also, use the LO-Z input, even if you don't choose to go with coax
cable right now.

>3) a north-south run?

Sure, but that isn't the answer to your immediate problem.

Hi Rees,

The advantage found in using a tuner is that it can cure "deafness"
induced by nearby strong transmitters overloading your receiver's
front end (the first stages of amplification). Such a problem is
rarely obvious aside from the general sense of lack of sensitivity -
and yet this symptom is often the most definite cue. Many who choose
to ignore this necessity proudly proclaim how good their set is, not
knowing that it could be vastly better.

Even though you may not be tuned to the local AM transmitter a couple
of miles away, its strength can be 100,000 times stronger than what
you are attempting to tune in. This signal will force its way into
your radio and develop a voltage called AGC which lowers your radio's
sensitivity - by design.

The solution here is to exclude that signal before it gets in, and to
include that signal that you want to hear so it can get in. This is
the function of a tuner. This function used to be part and parcel to
older non-computerized receivers (read tube-sets and expensive solid

state models). You can add it back in quite simply. Shop for the cheapest amateur radio antenna tuner that has two variable capacitors, and a switched inductor - and WITHOUT a meter. You can buy one with a meter, but the meter will not be functional for reception, it will probably cost more, but it will still suit the required function of tuning. There are sure to be SW specific tuners out there. They don't bring anything extra to the table except for smaller size, perhaps - and they could be expensive for no real advantage.

If you read this last paragraph closely, it gives a clue to a project you and your son could engage in: constructing a tuner from parts. Here's the simple list:

1. Box (any material, but metal is best);
2. Input connector;
3. Input capacitor with knob;
4. Switch with knob for coil inductor;
5. Coil inductor with taps for switch;
6. Output capacitor with knob;
7. Output connector.

That's it. Values for the components, how to arrange them, and where to find them can be left to investigation on the Web.

THANKS, everyone, for the very thoughtful and thorough responses!

John KD5YI wrote:

> Check for a slide switch on the back that switches from internal to external antenna.

Would that be the ATT 0dB - 20dB switch? They show it in a figure,
but don't say what it's for. I'll try it.

Sal wrote:

> Feedback to me would be nice. A Nobel Prize would be a bonus.

Your detailed suggestions of the antenna connections and
troubleshooting are quite helpful. I will return to them if the new
configuration doesn't work.

Jim Higgins wrote:

> Why aren't you connecting the antenna to the Lo-Z SO-239 connector
instead of the Hi-Z Motorola type connector? (Other than the manual
telling you to use the Hi-Z.)

Right. Apparently, Radio Shack improved the DX-394, but kept the
crappy manual. Getting the antenna higher would help, I'm sure, but
for now I'm stuck with what I've got.

Richard Clark KB7QHC wrote:

> If you read this last paragraph closely, it gives a clue to a project

I appreciate the suggestions. But I'm going to take the easy way for
now.

These have led me to try another configuration; what I'm imagining is
at http://i258.photobucket.com/albums/hh242/winwinsit/antenna2-1.jpg

The lightning arrestor I'm considering is at http://ba-electronics.com/a28.htm.

I'm wondering:

1) if this new configuration makes sense.

2) if I should use coaxial cable at A (between the tuner and the
lightning arrestor) since the connectors are SO-239 and PL-259? Or
should I just run more of the insulated wire?

3) about coaxial cable at B (from the arrestor to the antenna wire)?

4) if this antenna tuner would be adequate? MFJ-16010 at http://www.universal-radio.com/catalog/preamps/1329.html. If not, any other recommendations?

Thanks again!

Rees

> could put it to some good use.

Well, not sure what gauge wire it is, but I've been using cheap
speakerwire for HF dipoles with no problems whatsoever. Not certain,
but I think this is the stuff I use here:

http://www.jaycar.com.au/productView.asp?ID=WB1709&form=CAT2&SUBCATID=992#1

My prime HF antenna started out as a coax-fed 40m half-wave (10m/leg)
dipole made of this stuff in an inverted-V configuration. I used a
home made 1:1 voltage balun at the feed point. Over time, I moved the
feed point to near the back of the tuner with a short 3in length of
coax, and ran a random length of 300ohm ribbon to the feed point of
the dipole.

Later after reading about the G5RV, I extended each leg to 16m long.
It is important to note that while similar to a G5RV, my antenna does
not feature the same length of ribbon as a G5RV. The antenna is not
mounted up high, the apex would be at gutter level (we have a two-
storey house here). Legs tie off no higher than 2m in the air. One
end ties off to a frangipannie (sp?) tree in our front yard, the other
to a piece of rope running to a macadamia tree in our back yard. I
have a feeling the frangipannie is helping form part of the antenna.

This antenna, while quite deaf I find on the 10m band, has worked into
VK5 on 15m, I have had contacts into ZL on 20m, and it works quite
well locally on 40m and 80m. I have had successful contacts using QRP
power levels on 80m with this antenna, and it is very easy to tune
there.

It has broken once or twice. It has never taken me any longer than
about 15 minutes to repair and get back up in the air. It's also
cheap enough to consider being disposable, should disaster truly
strike.

So I say, go for it … it might as well do something useful.

Regards,
Stuart VK4MSL

Hey OM
The baluns I like to use are choke baluns and real transmission line
baluns, for ten meters and a 66% velocity factor coax that is 11ft of
RG213. That is 4:1 on ten meters only. And the high current, high
voltage nodes are at the ends of the coax.

1980. Coax balun

Newsgroup: rec.radio.amateur.antenna
Date: 2011-08-10 23:50:13 UTC
From: Wayne <mygarbagecan@verizon.net>
Message-ID: <j1v5g0$9qm$1@dont-email.me>
Source record: 4131

I found a 50 year old pencil drawn schematic that was done by an Collins Radio engineer. So....anyone ever use a coax balun as described below?

Wind a 3.5 inch diameter with 7 turns of RG-58. Space the turns such that the coil is 4 inches long.
Connect the output of an antenna tuner to one of the balanced feedline conductors. At one end of the coax coil connect the braid to the antenna tuner output, and the center connector of the coax to ground.

The other end of the coiled coax: connect the center conductor to the other balanced feedline conductor. Connect the braid at that end of the coil to ground.

Comments?

Sounds like a pipe-dream.

It would make more sense if two coax baluns were used, symmetrically.

Many people have. It's also often referred to as a "common mode choke".

One nice characteristic of them is that they don't contain ferrite or
iron cores which could saturate (and create distortion and harmonics)
at high RF current levels.

>Wind a 3.5 inch diameter with 7 turns of RG-58. Space the turns such that

I'm not sure why he specified hooking the braid to the tuner output
and the center conductor to ground. Most people do it the other way
around (it's easier to connect to a PL-259 that way).

Doing it his way brings the "hot" side of the tuner output out closer
to where one might touch it... there may be more of a risk of a shock
or flashover-to-ground situation here, if the SWR on the line is high
and the tuner is looking into a high impedance at the input of the
choke.

This may not be an issue in your particular deployment.

>
>Comments?

http://www.hamuniverse.com/balun.html shows numerous variations on
this same basic idea, and there are about a zillion others out there
on the Net and in the literature.

There are numerous variations:

- Single-layer solenoid-wound (as in the one you described), either
close-wound or spaced.

- Multiple-layer solenoid-wound.

- Scramble-wound.

Different winding style will give different amounts of inductance, and different (sometimes very different) amounts of distributed capacitance.

If I understand the situation correctly, a winding style with low distributed capacitance (e.g. single-layer solenoid-wound with space turns) functions primarily as a common-mode inductive choke... fairly broad-band, *if* you have enough turns to give you the necessary amount of common-mode inductance.

A choke which is multi-layer (perhaps even scramble-wound) can have more distributed capacitance, and it can act as a parallel-resonant trap at certain frequencies... giving a nice, high choking impedance at those frequencies. Above and below that resonance, though, its impedance can drop off fairly rapidly, and it may not choke the line effectively. Coaxial chokes of this sort are (I believe) often wound to give optimal performance on one or two bands.

[I could well be wrong about these details... it's been a while since I looked at this subject in any detail.]

Wayne, the device as you describe it is a form of balun (being a device that facilitates a transition between states of balance).

Considering the ATU output terminal to have voltage V, V is applied directly to one feedline conductor, and if the common mode impedance of the coaxial choke is sufficiently high and its length sufficiently short, approximately -V to the other conductor... so it implements a 1:4 impedance transformation.

The problem is with the "sufficiently" qualifications above. The common mode impedance of a coil of coax like this has been well explored, it has a very high impedance over a narrow range near resonance, and mediocre to low away from resonance, and so not well suited to broadband use.

Nevertheless, these types of things have appeal to those who are prejudiced against ferrite, or who just do things on the cheap.

I hasten to add that I have used just such a coil of coax as a single band 1:1 current balun, but it was carefully resonated for the band in use, and it measured much higher common mode impedance than practical ferrite cored baluns.

Mentioning current baluns, you describe a balun that could not be categorised as an effective current balun, as if you were to ground the side of the load direct connected to the ATU, the whole thing fails.

I know that to many there is a magic to all things that came from Collins, but you don't see this widely done, and for good reason.

Owen

I have had success using a construction similiar to:

http://www.arising.com.au/people/Holland/Ralph/CM4Balun.htm

Two coils are made out of two pieces 75 Ohm coax, each 4m long.
As coil forms i'm using tubular foam pipe isolation. I dont know
the correct word for them in English ;) The type used has a diameter
of 6 cm.

These baluns has served me well. Using TV-coax, the whole construction
wheights very little.

FDC FD-880 Dual Band 136-174/400-480Mhz FM Radio
http://www.409shop.com/409shop_product.php?id=106081
Special features

Dual band,dual Freq.,dual display and dual standby
Working Mode:U-V,U-U,V-V can be set freely.
Band can be set freely on the same channel:VHF TX-UHF RX or UHF TX-
VHF RX.

PTT ID function;DTMF function
Offset Freq and Freq.shift direction can be set.
Keypad lock (Auto/Manual);Busy channel lockout

Water-proof;Wired clone function
Built-in FM radio;Led flashlight
3 displaying modes selectable(CH,FREQ,CH Name)

VOX function;Stopwatch function
Priority Scan;Multiple Scan modes;Adding channel scan
Emergency Alarm function;Wired clone function

Reverse freq.function
Multipe Step frequency(5/6.25/10/12.5/25/50/100KHz)
Charging directly from the power supply.You can also
charge your radio by connecting the supplied ac adapter directly to
your radio.

Technical specifications

Model NO. FD-880(Dual-band)

General Frequency Band VHF UHF
Frequency Range 136-174MHz 400-480MHz
Channel Capacity 128
Operating Voltage 7.2V DC ±15%
Antenna Impedance 50O
Channel Spacing 12.5kHz/25kHz
Working Temperature -30 ? - +60 ?
Frequency Stability ±2.5 ppm
Size (Without Antenna) 104(W)mmx62(L)mmx36mm(D)
Weight(With Battery) about 250g
Battery 1500 mAh(Li-ion)
Transmitter RF Pwr Output 5W/4W
Modulation Type F3E
Modulation Distortion < 5%(300-3000Hz)
Max Freq Deviation < 5kHz(1000Hz When 100%)
FM Noise <=-45dB

Receiver
Sensitivity (12Db SINAD) 0.16μV
Selectivity 55dB
Adjacent Channel Selecivity >=70dB
Noise Respond >=60dB
Communication Range 3-5km(Downtown),6-20km(In the Open Area)
FM Noise 30dB/40dB
Modulation Type 8K/16KF3E
Audio Power Output 500mW When Distortion Less Than 10%
Audio Distortion < 5%
Operating Bandwidth ±3.5kHz/3.75kHz
Standby Current < 12mA

Each Set PACKAGE CONTAIN

1 x FDC FD-880 (VHF136-174 / UHF 400-480Mhz Dual Band)
1 x 7.4v 1600mAh Li-ion Battery
1 x Dual band Antenna.
1 x Belt Clip.
1 x ENG Manual
1 x Wall Charger PSU (Provide PSU plug for your Country)
1 x 12V Car Charger Cable
1 x PTT Earpiece for free

From: Sal <sobars@aol.com>
Message-ID: <j2258p$3s0$1@dont-email.me>
Source record: 4141

I'm sharing a good experience I had with LDG. At our local club meeting, Thursday, Aug 4, I bought an LDG AT-11MP. It's a discontinued item. At $10.00 it was a bargain but it needed two new front-panel toggle switches. They were physically damaged.

On Friday, Aug 5, I messaged LDG on their website and asked how to buy them switches. I said I'd send a check if they shipped with an invoice. The next day, while browsing in a surplus store, I found switches and put them in, so I messaged again, saying I had repaired the unit. I said if they had already sent me two switches, I'd honor the invoice and keep the switches.

Imagine my surprise when I got an email a few hours later (still Saturday) saying thar the switches were scheduled to go out but may not have been shipped. If I receceived them, I could just keep them! So apparently they weren't even going to invoice for them! A gift!

Life is Darn Good (get it?) and they made a new friend.

1992. Lightning arrestors

Newsgroup: rec.radio.amateur.antenna
Date: 2011-08-12 09:23:13 UTC
From: DrYattz <winwinsit@gmail.com>
Message-ID: <c09a0a04-61ed-424a-acaa-85ff0abdeb23@b34g2000yqi.googlegroups.com>
Source record: 4143

Having but recently returned to the world of shortwave radio, I'm trying to be better informed about technical and safety issues than I was as a kid. Now a homeowner with a mortgage and a homeowner's insurance policy, I'm worried about lightning protection. I'm receiving only, not transmitting. I have a ground rod just outside the window where the antenna wire enters, and I intend to disconnect the antenna outside the house when I'm not using the shortwave. But I want to be extra careful!

So I'm considering some options. Which make sense to you seasoned hams? Do any of these leave me open to my homeowner's insurance being voided if I get a direct hit by lightning?

I ordered this before I read the disclaimer: just "better than nuthin?"

http://www.universal-radio.com/catalog/protect/4618.html

The Opek A7516 Lightning Arrestor is not the "state-of-the-art" in radio protection. These "air gap" arrestors were OK for tube sets, but are not the best for today's solid-state rigs. However, if you are on a budget, this device is a whole lot better than nuthin! As with all lightning protection devices; you must connect it to an earth ground with thick ground wire, and it is not going to provide protection in the event of a direct hit.

So, here's a better gas-discharge arrestor:

http://www.universal-radio.com/catalog/protect/5611.html

The LDG SP-200 surge protector operates from DC to 1500 MHz with a 200 watt power capacity. The SP-200 protects coax feedlines from surges exceeding 230V, such as caused by nearby lightning strikes and static build-up. The SP-200 employs a gas-discharge tube that arcs-over when 230VDC is exceeded between the RF center pin and shield connections.

A variation, with different connectors:

http://www.radiolabs.com/products/antennas/accessories/lightning-protection.php

Ultra Fast Gas Discharge
0.4db Max Insertion Loss
350V or 90V Breakdown Voltage
VSWR Better than 1.5:1

Passes DC voltage
200W Operation

This doesn't say if it uses gas or air:

http://www.jetstream-usa.com/instructions/jtla1.pdf

Model # JTLA1
1.5-200 Mhz
50 ohm
8 kW PEP, 4 kW DC
Insertion Loss: Less than .1db
Surge Current Capacity 20,000 Amperers
VSWR Less Than 1.1:1 @ 1000Mhz
Voltage Attack Time: 0 to 10 Billionths of a second

Can I use something like this? It's designed for fences, but could
easily be rigged for an antenna input:

http://www.zarebasystems.com/store/electric-fence-accessories/la1

Protecting the fence charger from lightning strikes on the fence line.
This lightning arrestor creates a path of least resistance, diverting
lightning surges to the ground.

What's going on here?

http://ku5e.com/index-59869.html

The lower picture shows a device mounted atop the ground pole. Do you
recognize it?

Hi Rees,

For the Home:

If you implement an intention to control lightning hazard, I would
suspect a jury would see it your way if you sued the insurance company
for failing to uphold their policy with you. However, they might
grieve at yielding to the insurance's arguments against you.

It wouldn't get to trial if you could demonstrate that you met the
electrical code.

The elephant in the room is: have you properly installed that ground
rod? Driving a long one deep into the ground does not qualify for a
"yes" to that question.

Ground is a very complex and mysterious thing for many, many people.
The electrical code doesn't go any great distance to inform you of its
mysteries, but it does give you solutions that work.

For the Receiver:

As for protecting your receiver from the lightning risk presented by
putting wire up into the air. All of the lighting protectors you have
links to guarantee you will see a couple of hundred volts across the
terminals. The receiver is not going to survive. The distinction
between near strike and direct strike are not really material to the
problem of frying the receiver. The difference is merely one of
personal drama.

You may encounter this potential even on a seemingly cloudless day.

Receiver solutions:

Short the potential. This may be accomplish by using the "Folded Dipole" design of horizontal antenna. A "Folded Monopole" design for a vertical antenna. Other designs that employ loop coupling would also reduce the risk. All such options offer a DC short, but with an RF impedance. This insures static electricity drain, but allows an RF voltage (the short wave signal) to develop. A large inductor across the feedline or conventional dipole feed point provides the same protection. The coil acts as a DC short, but as an RF open.

Some SWL lightning protectors employ paired diodes to reduce the voltage risk to less than 10V - trivial indeed. Unfortunately, these same diodes will conduct in the presence of large RF fields (recall my discussion about nearby AM transmitters, and "nearby" is relatively near for RF but seemingly distant if you had to walk or even drive to it). This conduction will ruin listening opportunities with a jungle of mysterious signals "that shouldn't be there." Example, hearing an FM rock station feed on the 60M band.

Having a Tuner between your radio and antenna shifts the dynamics such that the gap arrestors are useful - until you throw the bypass switch.

I have written some notes about baluns in antenna systems at
http://www.vk1od.net/balun/concept/cm/index.htm . The notes explain why
a current balun is most suited to 'general purpose' antenna application.

In an ideal current balun, the current in each output wire should be
independent of whether one terminal or the other is grounded.

In the case of the balun describe, grounding one or other output
terminal has a large effect on output current in each of the wires.

Proponents of some balun designs insist that they work perfectly into an
isolated load. Of course, it the load is truly isolated, ie there is not
current path to ground from the load, then they are correct, but you
don't need a balun in that case because since the load is properly
represented by a two terminal network, the current into one terminal
MUST equal the current out of the other terminal. Problem is that real
antennas aren't necessarily will represented by a two terminal network
(though we often talk as if they are).

>weren't even going to invoice for them! A gift!

Nice people, nice company, and great service. However, the
justification may not be so altruistic. For small parts, the cost of
the parts may be insignificant compared to the handling. That
especially applies to returns. It would cost LDG far more than the
cost of the switches and postage to inspect the customer returned
parts, return them to stock, and deal with the paperwork. With
electrical parts, it's assumed that anything that has been in the
hands of the customer, has a good chance of being fried. Try
returning electrical parts to a hardware store or automotive supply
house, and watch the fun.

I had something similar happen with Digikey a few years ago. They
shipped me some parts, but the USPS(?) delivered the parts to the
wrong mailbox. After about 2 weeks, I was getting desperate and
called Digikey, asking for a duplicate shipment, which I indicated I
would pay for, and return the original package should it ever
magically appear. Digikey sent me the replacement parts at no cost.
Two weeks later, the original package appeared. I called Digikey
asking how to pay for the parts, or for return instructions. They
indicated that it was cheaper for them to just forget about the parts
and the added charges or to deal with the returns. So, I accidentally
received $70 in spare parts from Digikey for free. I like Digikey.

While I'm ranting on the subject, at a former employer, I once
calculated that the cost of shipping an empty box was $75. That's a
product with zero cost, but which still needs all the paperwork,
inspection, packaging, handling, billing, and overhead of any other
product. That means to ship a single transistor, the minimum the
company should have charged was $75. As a result of my calculations,
it became common for the company to provide massive quantity discounts
simply to reduce the number of orders by a given dealer. Pricing such
as:
1 xsistor $30
10 xsistors $35
100 xsistors $40
was common. There was also a trend to sell production extras by the
hand full or by the paper bag full as it was cheaper to do this than
to sort, separate, test, and re-file the random parts. Since all of

them were used in various radios sold and repaired by the dealers,
everything in the grab bag was probably useful.

Thanks, Richard!

But help me understand this:

> All of the lighting protectors you have
links to guarantee you will see a couple of hundred volts across the
terminals.

http://www.universal-radio.com/catalog/protect/5611.html says

* 230V DC discharge voltage ±15%
* Max 1000V surge (1x 40 µS duration)
* Max 6000A surge (1x 40 µS duration)

Which tells me that if the incoming current exceeds 230V, it dumps up
to 1000V and 6000A to ground. Right?

Rees

Sort of (voltage does not dump, so to speak).

Hi Rees,

The voltage in excess of 230V sustains the dumped current. The 230V
is still there, all the same.

That is to say that the resistance of the gap is (for all practical
purposes) infinite at voltages below 230V. For voltages applied that
exceed 230V, the resistance of the gap is 230V/2300A = 0.1 Ohm.

I chose 2300A both for ease of math, and as being representative.

Hence the gap undergoes a astronomical change in resistance in a very
short time (about a microsecond or less).

This is great fortune to the house's protection. This is poor fortune
to the radio's first transistor which resides in an environment of, at
most, 9V to 12V as a supply for gain, and 0.5V as typically the
highest voltage seen at the input. Transistors are rated to sustain
higher voltages, typically in the 10s of volts, sometimes higher.

230V to 1000V surge (as guaranteed) offer a speedy death. Of course,
of the original source being orders of magnitude greater, lightning
boosts speedy death to instantaneous (within nanoseconds).

Let's take a scenario closer to experience, and one that could easily
be likened to a near death experience at that. Open the hood of your
car, grab an unconnected spark plug lead with the end just a tenth of
an inch from the engine block (a common test of the ignition system).
You observe a spark. Dare you hold the metal clip where that spark is
jumping from it to the block? Dare you even hold the lead on its
insulation? The gap guarantees a certain voltage, and the system
guarantees a certain current (otherwise you would be forever stalled
in the driveway).

Why the hesitation in holding this lead, IF ALL the voltage and
current is dumped into the block? Experience will inform you of why
you hesitate, and why the transistor fears elevated potential.

An antenna invites access to elevated potentials from many sources
other than lightning. Even on a clear day, a dipole can accumulate

enough charge to make the spark gap sizzle. This would be extraordinary circumstances in some parts of the US, and typical in other parts. Yet and all as this may be commonplace, radios still play and life goes on. There are many other factors to consider insofar as what the input transistor has to suffer or enjoy.

I have no experience with 4nec2 to speak of, but what it sounds like is for an optimizer to work, you must first describe (name as a variable) what characteristic you would like to vary until the optimizer achieved an optimal result.

One guess for a three element yagi, I would suspect you would name three variables, the elements, changing each by by an incremental length (another variable) at a fixed frequency (another variable) for maximum gain (another variable) in a particular direction (another variable). Having said that little at seven variables (some fixed in value), it is quite a page full of algebra stated in a formulaic way for the optimizer (However, I fully expect that would be in a table description, not a literal formula).

Having said even that little, it lends a peek into the number of all the combinations and permutations of design this leads to. Each variable taken individually against all the possible others - and then repeated for the others in turn - leads to what mathematicians call Combinatorial Explosion (you don't have enough time to wait for the best solution). This is where constraints are added to the algebra, and you offer "close enough" as one of them to limit testing.

>Nowhere in the helps and getting started they explain that.
>I do not want to learn from examples, I rather work from the
>basics upwards. Would anyone learn math from a calculus
>formula without knowing the arabic numbers first?

Proving the validity of numbers consumed a volume of proofs back when Whitehead and Russell wrote "Principia Mathematica." It was logically dead on arrival BEFORE it was published - and yet it was the best description of simple math known. Calculus was simpler as it is principally symbol dominated.

Are you using symbols, or did you hard code all the dimentions in ft
or meters? The optimizer won't work without using symbols.

4NEC2 forums. Where to ask such questions:
<http://fornectoo.freeforums.org>

>Oh, how I hate this.

If it were easy, it would not be fun.
One must suffer before enlightenment.

>Praise Bill Gates for his user-friendly WINDOWS
>and to hell with all amateur softwares.

If you were around in the bad old days of computing, you might be
praising Bill Gates for saving us from the evils of big computer
companies. There was a time when you had to buy pre-formatted
floppies to work in DEC PC's, and when every machine had a different
floppy disk format. Anyway, your frustration with not reading the
manual and learning to use 4NEC2 has nothing to do with Windoze or
Bill Gates.

>Nowhere in the helps and getting started they explain that.

True. Found with Google in a few minutes:

4NEC2 tutorial including optimizer and evolver:
<http://heplx3.phsx.ku.edu/~dzb/antcal/nec-files/_GetStarted.txt>
See section 5.

Video of optimizer (25 min):
<http://www.youtube.com/watch?v=kYy6Yur127A>

>I do not want to learn from examples,

Then you will fail or at least be more frustrated. Hacking your own
path throught the wilderness is far more work than following in
someone elses footsteps.

>I rather work from the
>basics upwards. Would anyone learn math from a calculus
>formula without knowing the arabic numbers first?

Most certainly possible. There are numerous tools the devices that I use with only a minimal understanding for how they work. For example, there are many drivers on the road that could not even begin to explain how a gasoline engine works. (Hint: Carnot heat engine). I suspect that such basic knowledge would not improve their driving ability.

>Am in a baad mood tooday.

Have a better day.

2013. omniangle oa144

Newsgroup: rec.radio.amateur.antenna
Date: 2011-08-13 21:15:29 UTC
From: G8PSZ <g8psz@mailshackNOSPAM.com>
Message-ID: <j26pgq$516$1@speranza.aioe.org>
Source record: 3963

Hi, I am in the UK & am interested in trying a Par Electonics Omniangle OA-144.
I have come up against the problem in that they are not available here, I know Universal Radio used to stock them , however they are listed as discontinued, they would not export to UK anyway.
I have been in touch with Par Electonics , who manufacture them & have been advised that they will not export to the UK either, they also stated that they only deal with Amateur orders about 7 days a month on a variable basis , so even if I came over, I could not guarantee to hit their ordering period.
So I have 3 questions,

1. Has anyone got a surplus OA-144 they would be willing to export to the UK

2. Would anyone be prepared to source one from Par Electonics & export it to the UK

3. Has anyone got the technical details for one, particularily what is in the matchbox, is it only a 1:1 current balun or is there other jiggery pockery going on in there, so that I could attempt a hombrew version.

Rees,

The use of a device such as this that purports to protect the radio from a differential signal impressed across one interface could lure you into a false sense of security.

It does not eliminate the effects of elevation of the 'grounded' sided of the interface above real ground, and especially relative to other equipment. Of course, if the radio has more than one interface (eg a power lead), the problem is much greater than protecting it against a differential transient on that interface.

It is entirely possible that you do such a good job of protecting the input interface, that the receiver is destroyed by a transient from the power cord (if it uses one). You must take the bigger picture into account.

Then there is a question of the damage threshold (current / time profile) for the interface, the expected current waveshape, and the response characteristic of the device.

Whilst a high performance FET might be destroyed long before a gas tube fires, even one doped with radioactive isotope, on the other hand, the input stage of a HF receiver with the input attenuator in circuit might survive without protection.

It is a really complex problem, and the risk is that spending some small money migth delude you into a false sense of security.

I am with Richard, don't take less than competent measures for possibly worse outcomes.

I am making progress, though.
Got the optimizer running and edited a few of the example files
to have the variables selection available.

Works.

Now I watch the optimizer quickly de-optimizing the antennas
until they radiate into the wrong direction or get stuck in a
circular radiation diagram. In one case the optimizer bent
and rotated the dipoles around, I bet no specialist can do what I can.

Real fun, that is :-)

Yeah, thats good. Sitting back and watch.
Thanks for the idea of watching the Youtube demos.
Better than endless trial-and-error.
My goal is to find out what makes a direction finding antenna
different from a gain optimized antenna.
F/B ratio is all that matters for ARDF, for example.
Gain is secondary and side-lobes should be absent.
I must get that NEC working by all means.

That's easy (having helped design 2 commercial direction finders). Low side lobes and good front to back. Gain is well down the list of requirements. Side lobes will drive any direction finding scheme towards insane results by generating false peaks in the direction. The ability to recognize these is a function of how much time you want to put into the software. Reflections will also cause problems, but more so with side lobes.

To prove a point, I once threw together a rotating antenna direction finder using a low gain directional antenna (but with low side lobes, and no rear lobe). Due to the low gain, the -3dB beam width was a rather wide 60 degrees. I rotated the antenna slowly, and the computah made lots of signal level measurements. The result was that I could determine the direction within about +/-2degrees. Of course a higher gain antenna would resolve the signal direction much better, and could probably be rotated faster, but all would be much larger. However, there's a problem. High gain antennas tend to have boresight errors. Small asymmetries, such as mountings, gamma matches, and baluns, will have an effect.

>F/B ratio is all that matters for ARDF, for example.

F/B could be considered a side lobe at 180 degrees. Like other side lobes, it needs to be minimized.

>Gain is secondary and side-lobes should be absent.

Absent is difficult. Minimized might be a better goal. With a log amp driving the signal level measuring device, three orders of magnitude should be sufficient.

>I must get that NEC working by all means.

Slow down. Such things take time.

What manner of direction finder are you building and what frequency? Doppler? Rotating antenna? Phasing? Time difference of arrival? Homer? Adcock? Ouija board?

Sorry, bad mood again.
Watched the tutorials on Youtube.
Remarkably he starts loading an antenna and then deleting the elements
to get a blank builder screen.
The 4nec2 cannot start with a "new" file, it must load something from
before. Only then I may select NEW. This is a bug.

I copied the moves from the tutorial on my NEW antenna,
and I cannot place a source on the dipole. Does not work.
No error message, nothing.
So I will load some old antenna, delete everything and try again
as shown in the tutorial.

Within 5 minutes of work I have a list of 5 errors,
program errors, repectively bugs, mis-leading the user.
Can't type as fast as the bugs occur, I just described only one.
Of course I have no right to complain because it's free.
Yeah.

Now I watched the tutorial again and again
http://www.youtube.com/watch?v=3AqMq0J3WBc
and after 14:11 he adds a voltage source.
He does a horizontal movement with the cursor on the dipole wire
and only then the 4nec2 will place the voltage source on the dipole.
He does not mention that or explain that move.

This stupid bug -and a program bug that is, and a large one-
this stupid bug has cost me 2 hours of struggling.

Ready for the next bug.

I'll see if I can get pix on a web site I'm working on. You use cable ties doubled up inside the barrels to hold the wires. The Write Bros. pen barrels are about 5" not including the swage, and if you cut it in half, 2.5" should be ok for up to 10M.

It is a lot of pens. My recently deceased aunt was housebound, and did a lot of puzzles, crosswords and such. She also did a lot of letter writing. She had saved all of her pens for me, and when I took over her house, I found several packages of Bic pens. With #18 wire you can get two spacers from each pen. Not to waste anything, you can remove the ink cartridges with pliers, and keep one or two barrels for writing.

Well, there is no "new" button or choice under "File". Ask Arie Voors
for the feature. It seems easy enough to add to the program.

>I copied the moves from the tutorial on my NEW antenna,
>and I cannot place a source on the dipole. Does not work.
>No error message, nothing.
>So I will load some old antenna, delete everything and try again
>as shown in the tutorial.

Well, I've never had that problem because I don't try to "paint" the
antenna using the isometric or 3D views. It's not accurate enough
unless you snap to a grid. I create the antenna either externally,
with a text editor, or using the spreadsheet style editor. I import
that into 4NEC2 and make any necessary changes (and fix any screwups).
For geometric shapes, I use the external shape generator, which will
do surfaces, parabolic dishes, etc. 4NEC2 is not a drawing program.

>Within 5 minutes of work I have a list of 5 errors,
>program errors, repectively bugs, mis-leading the user.

Impressive. You might want to search the 4NEC2 forums to see if any
of them have been previously reported.
<http://fornectoo.freeforums.org>
Note that there is a section specifically for requesting new features.

>Can't type as fast as the bugs occur, I just described only one.
>Of course I have no right to complain because it's free.

In my limited experience, people complain more about free software
than paid software. That's usually because the author(s) encourage
feedback in order to improve their product.

>Yeah.

Thanks for ignoring my questions.

Nobody does backups until after they have lost data. I've been using
4NEC2 for at least 7 years and have never lost a file. Well, I have
accidentally overwritten a file, but that was my fault. When I tinker
with antennas, I save multiple versions of the same design with the
version number appended as in file001.nec. This way, if I make a
horrible mistake, I can go back to a previous version and try again.

##########"Backup, you say it". ##########

When optimizing for F/B also 4nec2 results in a too short driven
element, same as YAGICAD, they obviously use the same formula,
(a long two-liner) from literature.
I actually built antennas following that prescription,
and they do not work without additional corrections,
e.g. a very long hair-pin match.

Imagine a 3 element 2 meter yagi,

```
| | |
| | |
| | |
| |
|
```

Something is wrong here with the capacitive driven element.
Now I am having a hard time, because I want to find out in
what differs a gain optimized vs a F/B optimized antenna
and it is questionable whether that can be done with software.
Have not tried other programs yet.

http://imageshack.us/photo/my-images/837/snc14096a.jpg/

The Front to Back ratio is very frequency dependent
http://imageshack.us/photo/my-images/220/fbratio.jpg/
(Without the hair pin match)
http://img5.imageshack.us/img5/3479/snc14112hairpin.jpg

Therefore I put the driver on a slider
http://img841.imageshack.us/img841/8530/snc14097small.jpg
which allows to adjust the working frequency of the antenna
over a >10 MHz range on 2 meters. Adjust for minimum reception
from the back and the antenna is optimized for that frequency.

Now I want to collect a list of recipes which allow to build the
antenna without having to tweak it on the antenna analyzer.

A similar design once was offered by DIAMOND MAY1000
http://www.rfparts.com/diamond/MAY1000.html
Look at the frequency chart
http://www.rfparts.com/diamond/pdfdocs/MAY1000%20Adj%20Chart.pdf
With that antenna one could adjust the element lengths *and*
the distance between the elements, which is crucial for the F/B ratio.

A Yagi with fixed element positions can only be used for 1 frequency
(within a very small range) and therefore may be impractical
in many situations. The CEBIK tape measure antenna with their
water-pipe construction could be easily modified with a moveable
center element.

Helmut,

your ranting and raving about 4Nec2 seem entirely unfair, the 'bugs' that you complain do not seem to be bugs at all, just the way the program works; which is not to your liking.

Placing sources requires that you click whilst away from the wire and then drag the source onto the wire. This is not a bug, just the way that the author chose to do it.

In many years of using 4Nec2 I have never had it loose a file, so I can only assume that there is some sort of problem at your end.

Yes, it would be nice to have a 'New' button, but again not a bug, just the way that the program works. If this minor inconvenience pains you that much ask the author to add one.

Regarding optimization the phrase 'garbage in garbage out' springs to mind. Optimizers are just that, optimizers, they WILL NOT take a rubbish design and turn it into the perfect antenna.

Optimizers rely on finding minima (or maxima) in the set of parameters that you supply, so unless you are close to a good design it is very likely that they will 'get stuck' in a local minima and then home in on something other than an optimum design. So you have to have a good design to start with and also not try to optimize to a set of unrealistic goals. This applies TO ALL optimizers not just 4Nec2.

Regards
Jeff

So, the software is not perfect... but some of your complaints are are result of your own ignorance of modelling, NEC and 4NEC2.

Helmut, your vitrolic rant doesn't strike a chord with me.

Right now, Arie has some personal issues that we would all rather not have in our lives, and yet he is finding time for some problem resolution.

Arie, I dips me lid (that means "hats off" in Oz).

Show me the place in the manual or help where that is described.
Normally we do drag and drop, but here we must drag, drop & move.
Made me crazy, but no longer now since I know it,
and I will keep it a secret and not tell anyone.

Firstly it is not 'drag, drop& move'; it is click, drag & drop! Try
reading the Help a little more closely, you will find that it says:

"The next thing to do is add a voltage-source. While still in Add-mode,
click the 'Source button' (right of the 'Wire button'). Next click and
hold down your left mouse-button somewhere in the picture-box. At the
current mouse-pointer position a new source-object is displayed. Drag
the source-object to the middle of the second wire, just between the two
lower wires-ends of the feedline and release the mouse-button. When
properly positioned a new source is now added."

No one else reports this problem so draw your own conclusions!!! The
fact that it is free has no bearing on it.

Have you contacted the author and asked for this feature? No? I thought
not. Again the fact that it is free has no bearing.

Yes that is the way it is with ALL optimizers, not just 4nec2; gigo.

No one is forcing you to use 4nec2, however, no one else seems to be
having the problems that you claim are 'bugs', perhaps you should have
more patience, read the help more closely, and not be so quick to criticize.

It does not work as described, when inserting a source on a dipole
wire in the center segment, one of the first things to do in Example1.

Utter Rubbish!!! It works EXACTLY as described!!!

Hold down the left mouse button, drag the source to the segment where
you wish it to be, release the button - exactly as described!!!

Does your model have symbols defined (using the 4nec2 specific SY card?)
That's what it uses to populate the list.

Which editor are you using? If you already have a NEC input deck, it's
easiest to use the non-graphical editor.

What are you optimizing for.

Sure, you can whine about wanting better help files, but face it, Arie
is providing the product for free. If you are already proficient in
NEC, the help provided is fairly useful. If you are learning if from
scratch, yep, it's a pain.

Then when you set up your optimization criteria in 4nec2, weight the F/B or F/R with 100% and the others with zero (although sometimes, you may want to weight forward gain at 10%, just to keep it from driving to zero gain)

Unlikely...
4nec2 is just driving the finite element NEC engine underneath. YagiCad
uses analytical approximations.

NEC is *very* sensitive to segmentation, spacing, and wire diameters,
etc. particularly when close together or angled. The NEC4 engine is
quite a bit better, but you're probably using the default free NEC2 engine.

To effectively use this kind of thing, you need to be pretty aware of
the limitations and peculiarities of the underlying FEM codes. While I
wouldn't expect someone to have read the theory manual for NEC2, you
might want to check out some of L.B.Cebik's writeups on using MoM codes,
or the stuff in the ARRL Antenna Compendium from time to time.

> Something is wrong here with the capacitive driven element.

Depends on what you were optimizing for.
If all you said was "drive F/B to maximum", then it won't try to get you
a decent match, all it will do is drive to having element currents that
optimize for F/B, which will almost certainly have an evil feedpoint
impedance.

> Now I am having a hard time, because I want to find out in
> what differs a gain optimized vs a F/B optimized antenna
> and it is questionable whether that can be done with software.
> Have not tried other programs yet.

What I do is not try to use the optimizer to design the whole antenna including matching network. I optimize the basic element design first (without matching network). Then I add the matching network, hold the element spacing and length constant, and let that optimize. Then I go back and allow element length to change, but hold matching network dimensions/component values (I tend to use lumped element matching networks) fixed.

It's an iterative thing because it's tough to specify an appropriate optimization cost function with a simple interface. What you really want is something like "optimize F/B, but keep the feedpoint impedance >20 ohms and <100 reactive ohms"

>

this is just not true (otherwise the SteppIR wouldn't work.. it has fixed element spacing and works over a huge (>1 octave) frequency range) with fairly good performance.

One can also do similar with fixed spacing, and fixed length, and reactive loading of the elements at the centers.

> want to be extra careful!

Separate two issues:
1) having the house not burn down
2) protecting the front end of your radio

#1 is fairly straightforward and what your homeowner's insurance company might care about

#2 is pretty darn tricky, but the homeowner's insurance company doesn't care much about your radio.

As others will point out, a single rod pounded in does not generally a code compliant ground make. And a single rod pounded in might actually make things worse, as far as damage and destruction goes.

The goal is to get the lightning energy to go "somewhere else" than in your house. A secondary goal, since sending ALL lightning energy somewhere else is very difficult, is to not have the remainder destroy the radio.

First off.. almost all amateur antenna installations do not fully comply with the electrical code (and before I get flamed.. let me ask all you would be commenters: do you have a listed antenna discharge unit? are all your conductors no less than AWG 14 hard drawn copper or copper clad steel? Is your antenna lead in entirely contained within a metallic raceway? I thought not.. pace...we're going for practical here)

That said, I think that a "good faith" effort to do the right thing will help, and besides, unless you're in a disaster area, insurance companies generally don't work to try and deny claims on flimsy basis. there's the whole "reasonable person" aspect and your looking for decent information is a good start of what a "reasonable person" would do.

You might take a look at the safety chapter in the ARRL handbook as a start (the library has it, almost certainly, or you can find someone who will loan it to you).

A antenna discharge unit (open spark gap with a spacing of a few tenths of an inch) to a ground rod or rods will go a long way towards keeping most of the lightning current out of the house. It takes several kV to jump the gap, but once the gap is conducting, the voltage drops to a few tens of volts, and that's nothing in the overall scheme of things where there are many kilovolts along your wire.

The real problem comes in with the fact that no matter how good a job you do in connecting that gap to the rod, there's going to some distance, and some voltage drop between the voltage at that arrestor (during the strike) and "the rest of the house ground potential". If your radio is sitting in the middle, it WILL conduct, and it WILL be exciting.

The idea, then, is to make sure that no big voltages occur across two terminals of the radio (that could either be antenna and ground terminal, e.g. coax, or antenna and power supply).

The big deal is the AC power.. your wall socket is close to ground potential (in terms of kilovolts, anyway). So if your radio's antenna is at 2 or 3 kV, and the power cord is at ground, your radio will fry.

Run the radio off batteries? As long as you're not touching it, and it's not hooked up with an audio cable to your PC or something, then it just floats up to a few kV, and then, floats back down.

Most UL listed wall wart power supplies these days can hold off several thousand volts between inside and outside (that's the so called "hi pot" test rating).

Beyond that, it starts getting into gas tubes, and similar stuff to try and protect the innards of the radio. How much does your radio cost? Do you want to spend hundreds of dollars on surge suppressors to protect a $200 radio?

it's also remarkably hard to build a very sensitive receiver that will tolerate even a few tens of volts on the input.

That may be so at DC or 60 Hz, but it may be relatively transparent to the spectral components of lightning discharge current, components that may me significant to 100MHz or more.

There is no simple broadband equivalent circuit of the power transformer, but at 100MHz, it might look more like some series capacitance of the order of 100pF from primary to secondary for common mode excitation... and that may well allow damaging currents to flow (without insulation breakdown or permanent damage to the transformer), whether driven from the coax shield, the power line, or more likely, both.

Just another factor that makes design of bullet proof solutions so challenging.

Owen

God The Father says,
" If you go some place tonight and you say, 'Do
you know Who spoke at a meeting I was at?' and you
told someone in a loving way, they might even laugh.
But that's what they did to Moses. He said, 'I have a
Message, you must listen.' 'Who gave the Message?'
'The Almighty One.' 'Who are you, Moses, to have
Him speak? Who are you, for Him to use in such a
grand manner?' And I say to you tonight, Moses'
answer is and was the same as hers."

REVELATION DELIVERED THROUGH FRANCES M. KLUG
ON OCTOBER 23,1991

GOD THE FATHER

" In the time of Moses, when Moses stood
amongst people such as are present here tonight, he too
did not want to look or feel different in any form, in
any way, but when I took him to the mountain and I
held him there, he was in complete obedience to My
Will and My Way, My Words, My Direction, and What
I wanted delivered for a long time to come.

I gave him very little rest. I instilled in him a
great degree of knowledge, a great degree of wisdom
and a great degree of understanding, and an ability to
pass this on verbally, physically, mentally, emotionally
and spiritually, for the good of Souls. All the Words
that I gave to this man on a mountain were not delivered
fully by those who were taught What I wanted to be
taught.

Today, in the time in which you live, you have
much responsibility. Many men of all races, all colors,
all creeds, would say I would not use a woman, I would
use a man at this time in the world. How can man
decide what I would use, My Reasons for who I would
choose, and yet men stand in judgment, even on this
night, against this instrument who speaks My Words
distinctly, lovingly and purely, through the Soul, to you.

I use a Soul. The Soul, as Part of the physical,
is the manner which and how I speak to you. Many
men say, 'The Father would not speak.' Who knows
better than The Father, who would speak?

To speak through an instrument, men of all kinds would expect Me to shout. If I am angry I shout, but there is no reason to shout on this night to you, for the Soul I hold, the Soul I speak through, is as your Soul Who listens intently to My Words on this night.

I want you to read again and again the Words I spoke through this Specific Letter to all men.*

So many in the world imitate My Form of Ecstasy in a human being. Their manner of so-called acceptance to someone speaking through them has many versions and many false backgrounds.

Why would I not speak? You know I have spoken before. I use one seed to deliver My Will, My Way. The Soul accepts the Delivery. The physical says, 'God, not again,' but then submission of the will to My Will, What I Want Delivered, is important to Me.

Many men and women walk the earth, wanting a Special Blessing such as This, but I, your Father say, 'The degree of responsibility is beyond man's ability to discern; a Power a human body must accept at a time such as this, it is indiscernible by human standards.'

Thousands and thousands and thousands of Words have been given to you and others, telling of the responsibility of the Soul, That Portion of Me that is within each one here and in each human being throughout the world.

I will tell you something you could not recognize now, as My Words flow through this instrument who looks like you, feels many ways like you feel, but there would be a joy in the Words if the joy would extend to you happiness, laughter, and something to relax you so you could leave here and say, 'Wasn't that a fun time?' But I want you to leave here on this night and remember that it was a Blessed Time, a Blest Time, and a Time that is not always repeated in a lifetime.

It is not natural for a human being to want to be held so tightly, because the will wants the freedom to act, but it took a long preparation for this woman you know, to accept this manner of living, this form of speech, this acceptance of My Will, so you could be reached.

I give her moments of lightness, for the physical is extremely frail. The physical I speak through is fragile, and has become more so because of the Power that I use to reach you, for the benefit of your Soul, and to give you the strength to pass on to others, through

example, through words, through everything you do.

I have spoken much today, to give her the strength to be with you tonight. It has been a very tiring, difficult time, and what you do not know is she has just apologized because she was so tired, but she speaks like this to Me, but in truth, she would hide her tiredness from you; she always has, and you have My Word, she always will.

If you go some place tonight and you say, 'Do you know Who spoke at a meeting I was at?' and you told someone in a loving way, they might even laugh. But that's what they did to Moses. He said, 'I have a Message, you must listen.' 'Who gave the Message?' 'The Almighty One.' 'Who are you, Moses, to have Him speak? Who are you, for Him to use in such a grand manner?' And I say to you tonight, Moses' answer is and was the same as hers.

You are loved much. There is no preparation for My Words through her. My Words come with Love, Understanding, for you are children that I put in the world.

Every child born to the world is born for a purpose. Every child does not reach the fulfillment humanly expected, but I always look for that Soul to rise above all questions, all wrong, for you see, the enemy is always around, trying desperately to gather Souls, to take That Part of Me that I gave to you at the moment of conception.

You are blessed in many ways. Your presence here tonight is a blessing you could not understand. Your presence here tonight is your will as man.

I hold her deeper than you know. The body belongs to Me, because of the responsibility her will has accepted. I must give her time to relax after this ordeal for, in reality, the human body says, 'I feel I will break, my God, under this task.' So be it."

Designed to receive 54 Mhz to 210 Mhz ...
http://en.wikipedia.org/wiki/North_American_broadcast_television_frequencies
... Not going to work very well unmodified.

Keep the rotor and get an actual 2 meter yagi. I don't mean to discourage
you from building antennas. But you would probably be gutting that thing for
pieces of aluminum to cut to proper lengths to make a 2 meter antenna.

Cute cat. However the antenna seems a bit odd. The high carbon steel
tape measure elements are not the best for RF conductivity. Good
enough for receive, but I would check for RF heating in transmit.

The tape measure is also not a circular rod element. You probably
modeled it using a circular cross section. That's probably a good
first try, but if you want accuracy, the actual element cross section
will be needed. That's what I had to do with this stamped sheet metal
antenna:
<http://802.11junk.com/jeffl/antennas/mfj1800/>

>(Without the hair pin match)
>http://img5.imageshack.us/img5/3479/snc14112hairpin.jpg

>http://img841.imageshack.us/img841/8530/snc14097small.jpg

I presume the hairpin match goes between the wing nuts. Looking at
the photo of the hairpin, it seems small for matching a simple 2m
yagi. It's also a good idea to add a balun and to ground the center
of the hairpin match to the center boom.

No sir, your radio already knows that trick. It will feel that it is being cheated by you using speaker wire and will refuse to send RF out the antenna jack. (I'm just kidding.) :-)

But seriously it should work just fine. Treat it as insulated 18 gauge wire. I did use Radio Shack Flat copper Mega Speaker Cable as Ground Radials - I zipped them in half and each package made 2 radial wires.

Activate the source & add button, then click on the middle segment
and expect the source symbol to appear there.
It appears but vanishes in an instant leaving a highlighted segment.
If the sideways motion is not performed, you do not get it.
You have to pull it and that is counterintuitive.
The above description may be correct in that you have to pull
the object. After having worked with dozens of CAD programs
I did not expect such a trap.
Many users claim similar difficulties, the internet is full of them.
Honestly, who reads all the help files, hundreds of pages?

I know there are people who think every bug is a feature.
Those people do not live from their own work,
somebody else must pay for their living.

It took me 3 days to learn 4nec2 because of a long list of "features"
including data loss and program crashes. "Notify the author"
it suddenly says. The user sits there "What did I do wrong?"
which is a nagging question actually when the fault lies elsewhere.

All that counts is WALL CLOCK TIME.
But it's free.

In theory (from the simulations) the Yagi is rather narrowband.
Especially the F/B ratio is very frequency dependend.

The SteppIr does vary the elements, if I understand it correctly?
For practical reasons they do not change element positions on
the boom but sufficiently adapt to each frequency band.

For the same practical reasons I do it the other way round,
move the driver element in the 3 element yagi, and leave
everything else as is. This is intended for mobile direction finding.
Based on the Cebik pages and improved by making it tuneable
by moving the driver along the boom.

There is a story behind.
ARDF is a sporting endeavour, where people run around in
a restricted area searching for a defined signal, or several
foxes, as they are called. The antennas are optimized for the
fox frequencies. That's child play compared to real world.

One night I got a phone call from a desperate guy in Bosnia.
They had held a model flight competition there, class F1C,
and his model airplane flew ten kilometers away.
They put crash transmitters on the models and they
range in frequency from 140 to 160 Mhz without any approved
frequency raster, just what they can get and not to disturb
the neighbour model transmitter. So they need equipment for

a 20 MHz range. Most of them use amateur radio handhelds.
The transmitters weigh about 5 grams.

The Yugoslavian Balkan war was just over, where the killed 200000
people by shooting and cutting throats, and the mine fields were
still active and most of them still are today. They put fences around
and automatic siren warnings. That desperate guy's model airplane
was in or near such an area and night doomed. He has searched
for the whole day , was exhausted and could not locate it.
"Signals from everywhere and from all directions", he said.
That model was his only one for the competition and very expensive,
they cost a few thousand dollars.

"Signals from everywhere and from all directions."
That is a very interesting statement. Did you ever experience such
a situation? I had to place foxes and go after them to find out what
the problem was which the guy described. I expected an easy job,
because I am such an old fart in radio engineering. It was late summer
and corn standing two meters high, railway routes nearby,
high voltage lines criscrossing the landscape, buildings, hills,
mountains, fences, and now imagine it's getting dark and you are
in a foreign country where you never had been before,
between lakes, rivers, wet ditches and waste water canals.
I never knew that 2 or 3 meter high corn fields act as an antenna
array. The power lines and railways are wave ducts of extraordinary
quality, every metal fence collects and reflects and adds to the
reflections from the rocky mountains. Electromagnetic interference
overlays the fox signal until you only hear noise and crackles.
There you go. I hope the reader can imagine what is the difference
to a well planned amateur sport radio fox hunting event.

Quickly I recognized that a fixed-frequency ARDF antenna is
not suited for the task and one must be able to tune the F/B ratio
for the different frequencies the transmitters use, in combination
with a conventional attenuator. If your antenna receives from the
back, you will hear "signals from all directions".

Thank you for the links, appreciate your help.

I fear that in the end I will have to cut and tweak using the
antenna analyzer, and with the time perhaps find
"tape measure correction factors".
Want to keep the design as simple as possible,
and hope it works without a balun or additional tricks.
Am not yet sure if it will work that way, or not.

Well since the instructions on how to add a source are on page one, it would appear that you went to sleep earlier than you thought!!

Just because a program does not work the way that YOU expect, or perhaps would like, does not warrant the out and out rant that you started this thread with.

All of the information on how to run the program was actually there if you had bothered to read it rather than wasting time complaining about nothing.

Jeff

Should you read them?

Depends on if you want to make use of the program or not. for ANY modeling program (and any drafting program, as well) there's a fairly big first step in the learning curve.

And, because 4nec2 isn't a "drafting" or "drawing" program, it's UI doesn't follow the more common conventions. It's designed to make entering antennas easy for some subset of people. 4nec2 started with just using notepad to edit the NEC input deck and a formatted editor to edit cards.

Folks who start with EZNEC often find using raw NEC decks difficult, because they're used to the tabular model entry of EZNEC.

Folks who start with Visio, pre version 5, find modern versions of Visio a pain, because the UI changed to conform to PowerPoint.

Autocad is certainly not "intuitive" unless you've been using it a while.

For what it's worth, the 4nec2 help files are a whole lot better than the documentation for NEC itself.

Beyond the details of entering the geometry and simulation conditions (which are idiosyncratic for ALL antenna modeling programs.. no two are

alike, nor are the input file formats directly compatible, for the most part)

There's a fair amount of "art" in effectively using the programs and understanding the limitations inherent in the modeling technique being used (method of moments on wires for NEC). It's not just a matter of creating a bazillion segments and letting your processor grind away, because there's all sorts of subtle numerical precision issues.

4nec2 (and EZNEC) both provide some amount of help in keeping you away from egregious model errors (segment lengths that are unreasonable relative to wavelength and/or wire diameter).

There's also well known techniques for modeling flat surfaces with meshes that provide results that match actual measurement, even if the model doesn't "look" quite right if you render it.

NEC is very much a power tool like a chainsaw.. you can do things that you couldn't do with hand tools, but you can also do things that you don't really want. It takes some practice and background knowledge to use it effectively.

The value of purpose built modeling tools like AO is that they have a very constrained model space tuned to a particular application, so the program can
a) have a simple model entry (e.g. you can only do Yagi-Uda)
b) have a sophisticated objective function for optimization

NEC is a lot harder: you can enter any geometry from a simple wire to an entire battleship with 100s of antennas.

>Thank you for the links, appreciate your help.

Y'er welcome. However, I still don't have a clue what you're trying to accomplish. If you want super front to back ratio for a direction finding antenna, you need a wall, not a phased single wire reflector as in a yagi. Something like a dish or a panel reflector will work, but is probably not practical. As you discovered, the position of the reflector is very critical for maintaining the best F/B ratio. It's also very sensitive to frequency. You might be able to make it work with a flimsy tape measure, but it probably won't be very stable in the field.

Permit me to offer another idea. Instead of direction finding by the peak signal, do it with a null. Two identical dipoles, a T connector, and some coax, are all that are required. Space them about 1/4 wavelength apart. Insert a 3/4 wave coax phasing section between the two dipoles. Signals from the front antenna will cancel when they reach the 2nd antenna yielding a cardioid pattern. It will be just as critical and sensitive to frequency and position as your yagi, but methinks will work better. I've obtained 50dB deep nulls with this method. The good news is that you really only need one adjustment on the antenna, which is the relative distance between dipoles, which is easily accomplished by sliding the antenna on the boom. The adjustment range is limited, so an assortment of coax phasing lengths will also be needed. Adjusting the antenna for best null at a specific frequency, prior to transmitter hunting, is a necessary complication.

I also use this method on my home base station to null out a rather strong repeater, so I can talk to a distant repeater on the same frequency. I've also built one using 4 identical rubber ducky antennas for 2meters. It sorta worked but I could only get a 10dB deep null.

Both EZNEC and 4NEC have HF examples of this type of antenna.
cardioid.ez and \models\HFvertical\cardioid.nec

>I fear that in the end I will have to cut and tweak using the
>antenna analyzer, and with the time perhaps find
>"tape measure correction factors".

More bad news. You really do have to TEST your creations to see if the simulations and models are correct. I tend to make far too many

simplifying assumptions in my models, which show up as errors in the actual construction.

>Want to keep the design as simple as possible,

Simple is good. Crude is not. Recognizing the difference is difficult.

>and hope it works without a balun or additional tricks.
>Am not yet sure if it will work that way, or not.

It won't work well without a balun. The coax will radiate, giving unpredictable directional indications. You can minimize the effects with ferrite beads, a sleeve balun, or with just a coax loop.

yes.. although for the most part, if you're looking at the transient
from a "spark gap arrested lightning impulse" you probably don't have
quite that spectrum.

Could be.

Standler's book on transient protection comments that several studies
have shown that most modern consumer electronics can tolerate standard
transient impulses (both the 1 us and 6 us rise time variety) of several
kV. The not so halcyon ESD days of TTL gates connected directly to the
device connector pins are long gone.

Perhaps reading the Steppir patent might be illuminating:
<http://www.google.com/patents?id=rw6xAAAAEBAJ>
Note that the elements do not change position, only their length.

Exactly.. you can get very sharp nulls pretty easily. For simple antennas, there's usually an ambiguity, but you can resolve that by other means.

Hello Rees,

Mostly it isn't the problem to get sufficient signal, but to get
sufficient signal to noise ratio. If you can operate it outside the
house (with a seperate 12V battery), try this and see whether the
reception improves. Move around to find sweet spots. You may have
interference from indoor electronic equipment and this will be less
when you are outside. Don't run an extension cord to feed the receiver
as this may carry interference from inside towards the receiver.

As this receiver is rather sensitive, a large antenna may result in worse reception due to overloading the input circuitry. Here a so called preselector can help, expecially when you have some strong nearby transmitters. If you like constructing, building such equipment can be a nice project.

If outside reception is better, you may need coaxial cable to "transport" the antenna signal to receiver without picking up interference from indoor equipment.

Don't hesitate to come back with other questions or suggestions.

With the cardioid pattern, there's no ambiguity. With a deep null,
and a non-reflective environment, it's easy to use. However,
reflections off buildings and hills are a problem. The antenna is
roughly an omnidirectional antenna, and reflections will appear to
fill in the deep null. Not much can be done about that except to move
and try a different location. My favored method is by using a map.
Find a position, determine a bearing, and draw a line of position on
the map. Then, find a different location, and do it again. Repeat as
often as practical generating as many LOP's as possible. Some of the
LOP's will be totally insane, but a majority should cross at one point
on the map. (This has been automated in software, but a map is good
enough).

In 1976, I helped design the AN/SRD-21 homer DF, which DOES have a 180
degree ambiguity.
<http://802.11junk.com/jeffl/AN-SRD-21/>
If the homing receiver works in the same manner as described in the
above manual (PIN antenna switch, synchronous demodulator, charge
pump, and zero center meter), resolving the ambiguity is easy. Just
rotate the homing antenna to the right. If the zero center meter
indicates that you should turn back to the left, then you have the
correct direction. If it indicates that you should continue to turn
to the right, then you have the wrong direction.

This has nothing to do with the topic at hand, but I thought it might
be of interest. Some of my ancient comments on Doppler direction
finding:

I have seen recommendations that one do this by proceeding in a
straight line, taking bearings at positions of around 1/4 wavelength
or so. The effects of multipath will tend to cause the measured
bearing to wobble back and forth across an arc (as you go down the
line) and the true bearing will tend to be close to the center of that
arc.

I haven't tried this approach myself... but it might combine well with
your "take readings from lots of different locations" approach, by
helping cancel out some of the effects of multipath.

There's a photograph of this technique on a field with little flags at different distances all oscillating around a single line illustrating it in some ARRL publication (probably an antenna compendium, but maybe the handbook or antenna book).

On the schematic diagram that I retreived, the attenuator is only in the
path of the LO-Z antenna, the SO-239 jack -- the one with the threads on it.

The telescoping whip and the High-Z jack are electically almost the same
place, separated only by a single capacitor which couples signals from the
HI-Z jack into the path from the telescoping whip. No attenuator in that
path.

I think the photo was on interferometry for direction finding, where
they were trying to plot the wavefront pattern. I recall the photo,
but I couldn't find it in the ARRL Antenna Handbook (19th edition).
However, the handbook does have a full chapter on direction finding
(Ch 14) which includes the cardioid antenna.

The purpose of me using multiple bearings is simply to eliminate the
effects of reflections. It's not totally foolproof, but better than
chasing a single bearing.

There are better ways, but they're usually not very portable. A
rotating antenna direction finder can easily distinguish between the
incident signal from a reflection. Such direction finders display

something like the antenna pattern on a polar display. The incident signal is very steady and does not move in azimuth. Reflections jitter dramatically in both amplitude and azimuth. They also tend to appear and disappear rapidly and erratically.

Rotating antenna DF antennas:
<http://www.rockwellcollins.com/sitecore/content/Data/Products/EW_and_Intelligence/SIGINT/ANT-1040A_Airborne_Spinning_DF_Antenna.aspx>
<http://www.rockwellcollins.com/sitecore/content/Data/Products/EW_and_Intelligence/SIGINT/ANT-1040_Spinning_DF_Antenna.aspx>
20 in diameter, 25 in high, 50 lbs.

Another method that I've used is to generate a narrow "beam" using two identical yagi antennas that share a common reflector. The antennas are oriented about 20 degrees apart with the reflector at the vertex. A near perfect audible square wave drives two identical PIN diode switches on the driven elements. While the antenna may have a -3dB beamwidth of perhaps 10 degrees, the LOP of equal antenna signal levels is extremely sharp, and often less than 0.5 degrees. A synchronous demodulator, charge pump, differential amp, and zero center meter complete the systems. You can also do it by ear by listening to the null at the switching frequency. If the antennas and PIN diode switches are perfectly symmetical, all boresight error cancel. I originally contrived the system by reading about the Lorenz beam bombing system used by the German's during WWII, but later discovered that others had anticipated the idea.

Choice of device seems to be what you're concentrating on but I don't think the brand name of any device will figure into the solution at the insurance and electrical code level.

Correct bonding of the equipment ground/RF ground to the house ground at the entrance panel is the key for any of this. See e.g. W8JI's webpages.

Tim.

A popular scheme from WJ 30 years ago (at the advent of digital signal processing) used 3 antennas in a triangle, and basically did interferometry. Sampling the data and using an FFT lets you do a wide band at one time (which is handy if you want to DF frequency hopping radios, which became very popular in the 80s)

As far as VHF, I know a couple here in town I've seen using arrays
for direction finding. But they used four verticals in a square.
It worked quite well. We had one guy that kept jamming one of the
repeaters, and the user of said array was easily capable of tracking
him down to a shopping center parking lot where the guy was sitting
in his car. I suspect the expression on the jammers face when the
tracker tapped on his window was priceless. :)
The device in the car used an array of LED's in a cross configuration
if I remember right.
He had the antenna array on the back of his truck. I don't recall the
element spacing.

Likely a Doppler direction-finder, possibly a Ramsey DDF-1 or one of
the others of that sort.

They aren't perfect... definitely subject to errors due to multipath,
and they works best when looking for a relatively clean, non-modulated
carrier. Fun, though... I've used mine on several occasions to locate
sources of QRM or jamming.

I've seen similar 4-vertical arrays on the roofs of some police cars
in my area. I infer that they're used to track down cars which have
had their Lojack locators triggered, after a car theft.

You are correct with respect to LoJack, which radiates in the high VHF band. They do pseudo-doppler direction finding. I don't know how fashionable LoJack is these days... the sophisticated thieves know how to jam it. The widespread deployment of in-car GPS/cell (On-Star, etc) covers a lot of the other cases. Face it, most car thieves aren't all that smart.

Agreed. There are various commerical implimentations. Basically, the diameter of the "circle" of antennas controls the deviation of the doppler signal heard on the receiver. The bigger the diameter, that better the signal to noise ratio. Typical is about 1/2 wave diameter. Smaller diameters will work, but require narrower digital filters which slow down aquisition.

>They aren't perfect... definitely subject to errors due to multipath,
>and they works best when looking for a relatively clean, non-modulated
>carrier.

Plenty more wrong with doppler DF. They don't like horizontally polarized signals. Reflections cause false readings. Forward alignment (0 degree heading) varies somewhat with frequency. Switching PIN diodes in the antenna cause interpolation errors every 90 degrees. Multiple transmitters on the same frequency result in erronious readings. Antenna tilt causes big errors. Reflections off building and in particular, the ground ahead of the antenna, causes errors. There are fixes and work around for most of these, but I haven't seen any on ham quality dopplers. Some of my ancient comments on the topic:
<http://www.qsl.net/n9zia/doppler_notes1.txt>
<http://www.qsl.net/n9zia/doppler_notes2.txt>

>Fun, though... I've used mine on several occasions to locate

Ummm.... How did you get it to produce a usable bearing if there were two transmitters on the air at the same time? I can see if it you waited until the jammer was the only carrier, but few jammers allow that to happen. Mostly we use doppler for the traditional stuck transmitter.

Mini-rant: Why do almost ALL commerical radios have tx timeout timers, while almost ALL ham radios don't have this feature?

>I've seen similar 4-vertical arrays on the roofs of some police cars

That's LoJack. I rode around in test vehicle with one trying to make sense of the indication. In an urban jungle, it's very difficult to get a decent bearing due to all the building reflections. I suggested we try an elevated freeway, and the bearings improved. Works much better in the suburbs.

Is it because we're all known to be gasbags?

Timeout? Why the very *impudence* of that radio!!!

All kidding aside, we had a major repeater outage in San Diego some years ago. A 50w mobile, in the middle of a hotel parking lot, was on the air for hours, holdng the repeater. The T-hunters who found the car ID'ed the owner by his callsign plate and contacted him in the hotel. It was the old microphone-between-the-seat-cushions trick. Timeout would have helped that day.

A lot of the jamming in question is jamming of repeaters, so you are
DF'ing on the repeater's input frequency.

If you have a rough idea where the jammer is operating, you can often
get a Doppler detector (e.g. on a car) into that area and get a decent
signal from it when he's jamming... but be far enough away from the
person being jammed that you don't hear any of his signal (although
the repeater does).

A Dopper rig on the roof of a car has a far smaller line-of-sight
radius than a repeater receiver mounted up on a high building or
hilltop.

Yes. That's also why many Japanese ham radios are severely lacking in
microphone gain. I guess they assume that all Americans are always
yelling.

>Timeout? Why the very *impudence* of that radio!!!

Ok, bad choice of a name for the timer. Perhaps "anti-ratchet mouth"
or "monolog restrictor" might be better.

Yep. It's all too common. My guess is one every month or so.
Unfortunately, I managed to jam the microphone under the debris pile
that usually clutters the passenger seat, jamming the local repeater.
I was easily identified by the classical music in the background since
nobody else around listens to classical music. What's really
irritating are the number of packet radios that end up on repeater
frequencies. Usually, we can decode the call sign and contact the
culprit. Occasionally, there's no call sign as the owner is trying to
setup his TNC. There's also the stuck transmitter on commercial and
public safety frequencies. Those are fun and gets us plenty of points
from the various agencies. Extra credit to the local comm shop that
likes to defeat the timeout timer, for no obvious reason.

My favorite stuck transmitter was on marine channel 16. There was a
very strong carrier on Ch 16, that could be heard all over Monterey
Bay. Everyone dug out their DF hardware and the searching began.
Strong signal, no modulation, 100% duty cycle. This should be easy.

Right...

After 5 days of bad guesses and dead ends, the culprit turned out to be a marine base station on Fremont Pk (3,000ft). It was rarely used and was only functional in order to maintain the license. Something went wrong with the DC wireline control system (with no timer) which stuck it on the air. Why so difficult? The strong signal created a wide assortment of reflections. Everyone had trouble separating the strong reflections from the incident signal with the Doppler DF boxes. I was using my rotating antenna kludge, but stupidly used a 5 element yagi tuned to 146Mhz. At 156.8Mhz, I later discovered that it had almost as much gain towards the back of the antenna as it did in the forward direction.

Incidentally, there's another difference between ham and commercial mobiles. Commercial mobiles have a PL hang up function, where the receiver is in PL decode when the mic is hung in the hanger, and goes to carrier squelch when removed. Many ham mobiles seem to be missing this useful feature.

This is so the commercial operator listen to the whole channel (and not just his company's CTCSS filtered traffic) prior to transmitting. A typical ham channel is continuously monitored and everyone has the same CTCSS tone.

Sure, but we have several other distant repeaters on the same channels
I like to monitor. I also hear plenty of RF leaks and odd sources of
RF as I drive around. So, I turn on the PL decode. With a ham radio,
I just pickup the mic, the receiver stays in PL decode, and proceed to
talk. With the Maxtrac I currently use in the car, as soon as I
pickup the mic, I hear all the junk, which helps to make sure I'm not
causing a problem by talking over other users on the distant
repeaters. (We have somewhat overlapping coverage areas). Also, when
in PL decode, there's about a 600msec delay before the rx squelch
opens, which obliterates the first two syllables.

It does not seem the public safety radio devices always had this
timeout timer either.
Before the public safety services here switched to a digital system,
they used NBFM equipment from companies like Motorola, and it was very
common to hear stuck transmitters that blocked an entire repeater channel.
(which often consists of multiple receivers and transmitters over a city area)

Police used mobile transceivers in the cars on VHF and portables on UHF
so it usually was possible to alert the users on the other channel and
hope the stuck PTT key was found that way, but on major events like
queen's day it often happened that the portables channel was jammed for
half an hour or so before the culprit was found.

Of course the equipment was aging by that time, it probably was from
the eighties. Now they are all on TETRA and AFAIK that system allows
the operator to just tune out stuck transmitters or devices that fell
into wrong hands.
